the proposal of this family, the method employed was the 16S rRNA oligonucleotide cataloguing technique. Later, Dobson et al. (1993) obtained the 16S rRNA sequences of *Halomonas* (*Deleya*) *aquamarina*, *Halomonas* (*Deleya*) *halophila*, *Halomonas* (*Deleya*) *marina*, *Halomonas elongata*, *Halomonas meridiana*, *Halomonas* (*Halovibrio*) *variabilis* and *Halomonas subglaciescola* (sequence accession numbers <http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=M93352{M93352}>, <http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=M93353{M93353}>, <http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=M93354{M93354}>, <http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=M93355{M93355}>, <http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=M93356{M93356}>, <http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=M93357{M93357}>, and <http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=M93358{M93358}>) and analyzed them together with the sequences of *Halomonas halmophila* and other species belonging to the Gammaproteobacteria. They showed that the level of similarity among the sequences of members of the family Halomonadaceae is 92.6–100% and that the phylogenetic grouping did not correspond to the taxonomic assignment of the species analyzed, suggesting the unification into a single genus. They also proposed a number of characteristic sequence signatures of the members of the family Halomonadaceae that have been readapted in other studies (Dobson and Franzmann, 1996; Arahal et al., 2002a), as new members have been described. However, full-sequence analyses are much more informative than signatures alone since the latter have to be redefined on the basis of present and future new species.

Mellado et al. (1995b) conducted a phylogenetic study on six new 16S rRNA sequences ({X87217}, {X87218}, {X87219}, {X87220}, {X87221}, and {X87222}), corresponding to

Chromohalobacter marismortui (four strains), *Halomonas* (*Volcaniella*) *eurihalina*, *Halomonas* (*Deleya*) *salina*, and close relatives. They proposed the reclassification of *Volcaniella eurihalina* as *Halomonas eurihalina* but highlighted the need of a polyphasic approach to determine the natural taxonomic position of members of the Halomonadaceae, especially because their heterogeneity was (and still is) too large for a single genus.

Further studies by Dobson and Franzmann (1996) determined another seven 16S rRNA sequences ({L42614}, {L42615}, {L42616}, {L42617}, {L42618}, {L42619}, and {L42620}) corresponding to the type strains of *Halomonas subglaciescola*, *Halomonas* (*Deleya*) *cupida*, *Halomonas* (*Deleya*) *pacifica*, *Halomonas* (*Deleya*) *salina*, *Halomonas* (*Deleya*) *venusta*, *Halomonas halodurans* and *Halomonas* (*Volcaniella*) *eurihalina*. On the basis of their results, they proposed the unification of the genera *Deleya*, *Halomonas* and *Halovibrio* and the species *Paracoccus halodenitrificans* into the genus *Halomonas*.

Recently, Arahal et al. (2002a) evaluated the phylogenetic status of the family Halomonadaceae using 16S and 23S rRNA sequences. In addition to the new sequences determined in their study, 18 for the 23S rRNA (AJ306870, AJ306871, AJ306872, AJ306873, AJ306874, AJ306875, AJ306876, AJ306877, AJ306878, AJ306879, AJ306880, AJ306881, AJ306882, AJ306883, AJ306884, AJ306885, AJ306886, and AJ306887) and 7 for the 16S rRNA (AJ306888, AJ306889, AJ306890, AJ306891, AJ306892, AJ306893, and AJ306894), the sequences were compared to more than 16,000 full or almost full rRNA sequences. By that time, the number of those sequences that could be ascribed to the family Halomonadaceae exceeded 70 (including many sequences from environmental clones and poorly characterized isolates). In addition, several treeing methods were used to elucidate the most stable branchings. A good agreement between the 16S rRNA- and the 23S rRNA-derived trees was obtained. According to this study, the genus *Halomonas* was formed by two well-defined phylogenetic groups (containing five and seven species, respectively) as well as six species that could not be assigned to any of the above-mentioned groups. Group 1 comprised *Halomonas elongata* (type species of the genus), *Halomonas eurihalina*, *Halomonas halmophila*, *Halomonas halophila* and *Halomonas salina*, all bearing a 98.2% average sequence (16S rRNA or 23S rRNA) similarity. Group 2 included the species *Halomonas aquamarina*, *Halomonas meridiana*, *Halomonas magadiensis*, *Halomonas variabilis*, *Halomonas venusta*, *Halomonas halo-*

durans and *Halomonas subglaciescola*, and exhibited a 97.6% mean 23S rRNA sequence similarity (97.4% in the case of the 16S rRNA sequences). The species *Halomonas pacifica*, *Halomonas halodenitrificans*, *Halomonas cupida*, *Halomonas desiderata*, *Halomonas campisalis* and *Halomonas pantelleriensis*, not only do not clearly fall into either of the two groups mentioned above but also shared relatively low values of sequence similarity with them or even between themselves (91.7–96.7%; Arahal et al., 2002a). The phylogenetic data are in agreement with the phenotypic heterogeneity reported for the species of the genus *Halomonas* or the wide range of G+C content (52–68 mol%) described for the different species of *Halomonas*.

With respect to the genus *Chromohalobacter*, the four species described within this genus formed a group closely related to *Halomonas*. The average rRNA sequence similarity of species of *Chromohalobacter* is 98.6% (for the 23S rRNA) and 98.5% (for the 16S rRNA). Within this group falls the sequence of *Pseudomonas beijerinckii*, an organism probably misclassified. If their sequences are compared to those of other halomonads, values below 95% (generally accepted as a good borderline for genus separation) are obtained in all cases. Similar low values were obtained for the sequence of *Halomonas marina*, which forms a deeper branch of the *Halomonas-Chromohalobacter* group. Indeed, according to this and other data, this organism was proposed as the type species of a new genus, named “*Cobetia*” (Arahal et al., 2002b). Finally, the sequences of *Zymobacter palmae* and *Carnimonas nigrificans* show a deeper branching in the tree (Fig. 1). Their 16S rRNA sequence similarity is 93.5% and even lower values are obtained when comparing any of the two with the other members of the family.

In the meanwhile, five new species have been proposed within the genus *Halomonas*: *Halomonas alimentaria* (its closest relative is *H. halodenitrificans*; Yoon et al., 2002), *Halomonas halocynthiae* (which cannot be ascribed to any of the rRNA groups of *Halomonas*; Romanenko et al., 2002), *Halomonas marisflavi* (whose branch falls between that of *Cobetia marina* and the branch of *Zymobacter palmae* and *Carnimonas nigrificans*; Yoon et al., 2001), *Halomonas maura* (which falls into rRNA group 1 of the *Halomonas*; Bouchotroch et al., 2001), and *Halomonas muralis* (its closest relative is *H. pantelleriensis*; Heyrman et al., 2002; Fig. 1).

From the phylogenetic point of view, some well-defined relationships can be observed within members of the Halomonadaceae. These groups, as defined above, are stable regardless of the methodology employed. Other relations may

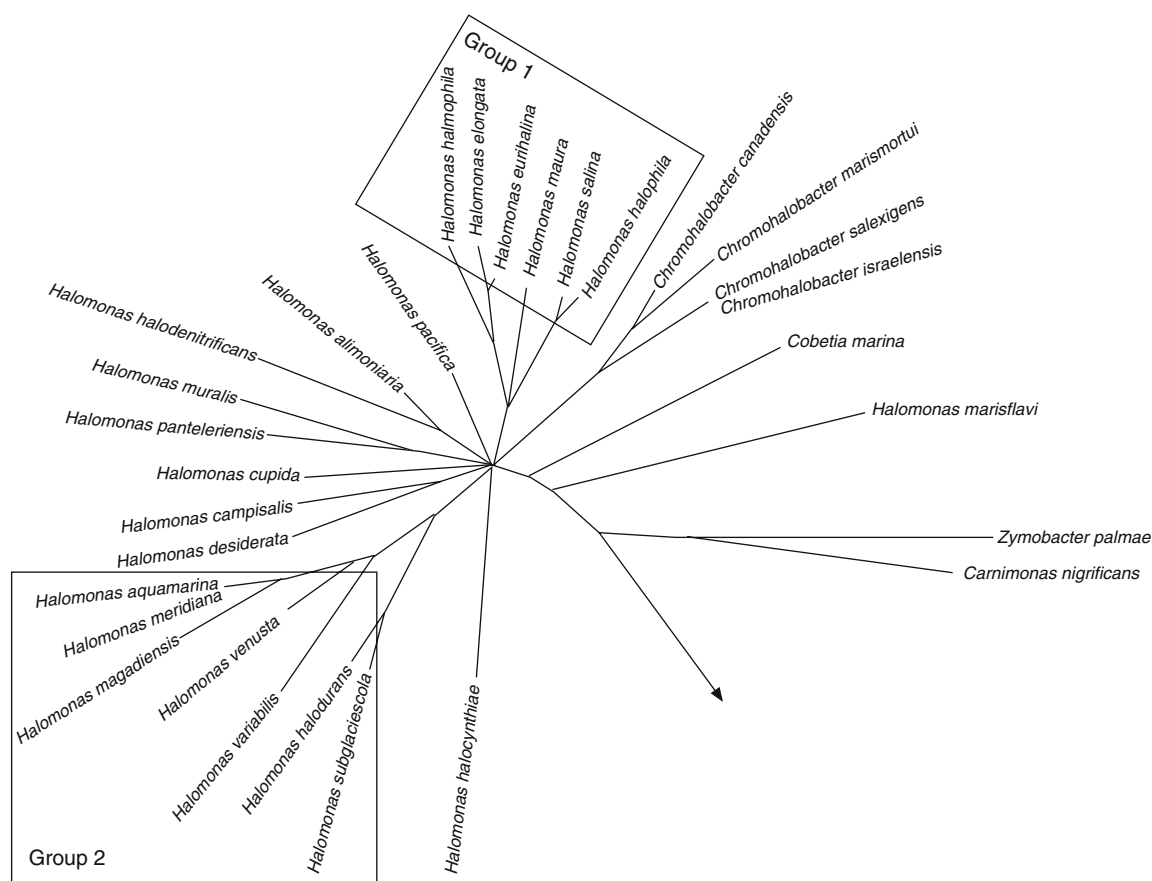

Fig. 1. 16S rDNA based tree of members of the family Halobacteriaceae. An explanation about the methodology followed for sequence analysis can be found in Arahal et al. (2002a). The arrow points to the outgroup, which has been removed to simplify the figure. (2002a) have been marked accordingly. Bar, 2% estimated sequence divergence.

become better defined once more in-between sequences become available.

Taxonomy

The family Halomonadaceae belongs, together with the “Alcanivoraceae,” and the “Oceanospirillaceae,” to the “Oceanospirillales,” an order within the Gammaproteobacteria (Garrity et al., 2003) that consists mainly of marine species.

The family Halomonadaceae was originally proposed by Franzmann et al. (1988) and it was later emended by Dobson and Franzmann (1996). At the start of 2004, this family included five recognized genera: *Halomonas* (type genus), *Carnimonas*, *Chromohalobacter*, *Cobetia* and *Zymobacter* (Garrity et al., 2003). Table 1 contains relevant taxonomic information on these genera and their species.

As mentioned before, some of the current species were isolated and described many years before the proposal of the genera *Halomonas* (Vreeland et al., 1980b), *Chromohalobacter* (Ventosa et al., 1989) or *Cobetia* (Arahal et al., 2002b): “*Chromobacterium marismortui*” (now *Chromohalobacter marismortui*), “*Arthrobacter marinus*” (earlier synonym of *Cobetia marina*), “*Achromobacter aquamarinus*” (*Halomonas aquamarina*), *Flavobacterium halmophilum* (basonym of *Halomonas halmophila*) or “*Micrococcus halodenitrificans*” (*Halomonas halodenitrificans*) are the oldest examples. In 1972, Baumann and coworkers published an extensive taxonomic study of Gram-negative, nonfermentative marine bacteria, including four organisms assigned at that time to the genus *Alcaligenes*, namely *Alc. aestus*, *Alc. cupidus*, *Alc. pacificus* and *Alc. venustus*. About one decade later, Baumann et al. (1983) proposed the creation of the

genus *Deleya* to accommodate those four marine species as well as *Pseudomonas marina*.

The genera *Halomonas* and *Deleya* served as the basis for the creation of the family Halomonadaceae (Franzmann et al., 1988). At that time these genera contained four and six species, respectively.

A chemotaxonomic study (Franzmann and Tindall, 1990) of members of the family Halomonadaceae concluded that on the basis of respiratory quinone, polar lipid, and fatty acid compositions, no clear distinction existed at the genus level. Only a few months earlier Ventosa et al. (1989) proposed *Chromohalobacter* as a new genus with a single species, *C. marismortui*, on the basis of a subculture of "*Chromobacterium marismortui*," isolated from the Dead Sea (Elazari-Volcani, 1940), and seven moderately halophilic isolates from a Mediterranean saltern in Spain that were found to be very closely related to it. Later, in the

phylogenetic study of Mellado et al. (1995b) it was concluded that this genus belongs to the family Halomonadaceae.

The genus *Zymobacter*, with its single species *Z. palmae*, was created by Okamoto et al. (1993) and placed later in the family Halomonadaceae (Dobson and Franzmann, 1996).

By then, 16S rRNA phylogenetic analyses were used as definitive evidence of the lack of correlation in the taxonomic arrangements within the family Halomonadaceae (Dobson et al., 1993). Mellado et al. (1995b) proposed the reclassification of *Volcaniella eurihalina* as *Halomonas eurihalina* and pointed out the heterogeneity of the *Halomonas-Deleya* complex. Dobson and Franzmann (1996) transferred all species of the genus *Deleya* to the genus *Halomonas* together with *Halovibrio variabilis* and *Paracoccus halodenitrificans*. In one way, this simplification stopped the confusion of the naming within the *Halomonas-Deleya* complex, but

the resulting genus, *Halomonas*, contained (and still does) very different species and it is considered too heterogeneous. The genus *Halomonas* was expanded to 15 species, with few characters in common, while the only two other genera recognized at that time, *Chromohalobacter* and *Zymobacter*, contained one each. Meanwhile, the genus *Carnimonas* was created by Garriga et al. (1998) to accommodate one single species, *C. nigrificans* isolated from cured meat products, and later it was included into the family Halomonadaceae (Arahal et al., 2002a).

In recent years the genus *Halomonas* continued to include new species since new descriptions were carried out. As of January 2004 there are 23 validly published species names. These do not include *Halomonas canadensis* and *Halomonas israelensis* (Arahal et al., 2001a), which were transferred to the genus *Chromohalobacter*, or *Halomonas marina*, which was proposed as *Cobetia marina* (Arahal et al., 2002b). The list of articles in press of the International Journal of Systematic and Evolutionary Microbiology (<http://intl-ij.sgmjournals.org/misc/pip.shtml>) include the proposals of several new *Halomonas* and *Chromohalobacter* species for which the following names have been proposed: *H. neptunia*, *H. sulfidaeris*, *H. axialensis*, *H. hydrothermalis*, *H. boliviensis*, *H. ventosae*, *H. anticariensis*, *H. organivorans*, *C. sarecenensis*, *H. koreensis*.

A valuable effort to address the taxonomy of the group from a different perspective than the prevailing one (that is, ribosomal RNA phylogeny), is the study of Mata et al. (2002). In this article, they present a detailed phenotypic characterization of the type strains of all *Halomonas* species recognized at that time and the intraspecific variation of four of those species by studying 87 additional strains. The authors compared the reactions of 234 morphological, physiological, biochemical, nutritional and antimicrobial susceptibility tests. Part of the nutritional characterization was obtained by using a miniaturized (Biolog) identification system. It was the first time that such a method was employed so extensively among halomonads. In addition to the new data that were presented in their paper, some differences were observed between their results and those from the original species descriptions. Numerical analyses demonstrated the phenotypic heterogeneity of the *Halomonas* species (Mata et al., 2002). An important conclusion of the study of Mata et al. (2002) is that phenotypic traits can be selected according to their usefulness for distinguishing *Halomonas* species. It would be desirable that future taxonomic proposals within the genus *Halomonas* reach the same level of completeness in their descriptions and that such studies

be extended to the other genera of the family Halomonadaceae.

Habitat

According the original description of the family Halomonadaceae (Franzmann et al., 1988), its members typically occurred in "temperate and Antarctic saline lakes, solar salt facilities, saline soils and marine environments." This is still true for the majority of the current species (Table 2). Indeed the only exceptions to the above definition are *Carnimonas nigrificans*, *Chromohalobacter canadensis*, *Halomonas alimentaria*, *Halomonas desiderata*, *Halomonas halodenitrificans*, *Halomonas muralis* and *Zymobacter palmae*. Of these seven organisms, only *Zymobacter palmae* is neither halophilic nor halotolerant (however, it is very tolerant to ethanol—up to 6%).

So, the halomonads can be found in any saline environment, regardless of its geographical location. This includes oceans and seas (even at considerable depths), saline soils, salty foods, naturally occurring saline lakes, solar pans, etc. Since some of its members are also alkaliphilic, they are found in soda lakes and alkaline soils.

On the genus level, not surprisingly, *Halomonas* is found to be the most ubiquitous genus with the largest number of species, and these are very heterogeneous.

As for the interactions of halomonads with other microorganisms, Ivanova et al. (2002) characterized a heterotrophic microbial enrichment community established during the degradation of brown algae *Fucus evanescens*, and consisting of two species, *Pseudoalteromonas* sp. and *C. marina*. While the first was highly metabolically active (14 hydrolytic activities could be detected) and likely plays the main role in the initial stages of algal degradation, the second, *C. marina*, produced only caseinase and DNase but was resistant to the bacteriolytic activity of the former and utilized the degradation products of polysaccharides.

More recently, in a study about the temporal stability and biodiversity of two complex antilisterial cheese-ripening microbial consortia (Maoz et al., 2003), out of 400 isolates, three were identified as *H. venusta*, two as *H. variabilis*, and two as *Halomonas* sp. by Fourier-transform infrared spectroscopy and 16S ribosomal RNA sequence analysis.

Isolation

Halomonads may be isolated following standard microbiological techniques on complex or

Table 2. Habitats of members of the family Halomonadaceae from which the original strains were isolated.

Species	Habitat
<i>Carnimonas nigrificans</i>	Raw cured meat products
<i>Chromohalobacter canadensis</i>	Contaminant on medium containing 25% NaCl

<i>Halomonas alimentaria</i>	Jeotgal (Korean traditional fermented seafood)
<i>Halomonas aquamarina</i>	Marine environment
<i>Halomonas campisalis</i>	Soil below a crystalline salt surface
<i>Halomonas cupida</i>	Marine environment
<i>Halomonas desiderata</i>	Municipal sewage
<i>Halomonas elongata</i>	Salterns
<i>Halomonas eurihalina</i>	Hypersaline habitats (soils and salterns) and seawater
<i>Halomonas halmophila</i>	Dead Sea
<i>Halomonas halocynthiae</i>	Gill tissues of the ascidian <i>Halocynthia aurantium</i>
<i>Halomonas halodenitrificans</i>	Meat-curing brines
<i>Halomonas halodurans</i>	Estuarine water
<i>Halomonas halophila</i>	Saline soils
<i>Halomonas magadiensis</i>	Littoral sediments of saline and alkaline East African soda lakes
<i>Halomonas marisflavi</i>	Marine environment
<i>Halomonas maura</i>	Saltern
<i>Halomonas meridiana</i>	Antarctic saline lakes
<i>Halomonas muralis</i>	Biofilm covering a wall and a mural
<i>Halomonas pacifica</i>	Marine environment
<i>Halomonas pantelleriensis</i>	Hard sand
<i>Halomonas salina</i>	Hypersaline soils, salt ponds, salt lakes, and seawater
<i>Halomonas subglaciescola</i>	Antarctic saline lake (Organic Lake).
<i>Halomonas variabilis</i>	North Arm of the Great Salt Lake, Utah (USA)
<i>Halomonas venusta</i>	Marine environment
<i>Zymobacter palmae</i>	Palm sap in Okinawa Prefecture (Japan)

defined media with a suitable salinity and incubated at room temperature for 1–7 days.

Since not all species show the same requirements (or tolerance) of salinity (Table 3), differences are expected to occur depending on the final salt content of the media. With the only exception of *Zymobacter palmae*, all species are able to grow at salinities in the range of 3.5–10% but not necessarily at their optimum over the whole range. Media for the selective isolation of moderately halophilic bacteria can be prepared with higher salt contents (for instance 20%) to prevent the growth of non-adapted competitors. The selectivity of such media can be increased by lowering the concentration of Mg^{+2} to prevent the growth of extreme halophiles (Ventosa et al., 1982). However, not all the species within the family Halomonadaceae are able to grow at such high salinities.

The growth of species of *Chromohalobacter* and some *Halomonas* such as *H. aquamarina*, *H. cupida*, *H. eurihalina*, *H. halmophila*, *H. halodurans*, *H. halophila*, *H. maura*, *H. pantelleriensis*, *H. subglaciescola* and *H. variabilis* will be favored in media with a salt content of 7.5–10%. Some of them will yield reasonable growth at

15% salts or even 20%. At these concentrations, growth of extremely halophilic Archaea can occur, but they are easily distinguished by their red pigmentation. Most of the above-mentioned species have a minimum requirement for NaCl of 1–3.5%.

Other species (*Cobetia marina*, *H. alimentaria*, *H. campisalis*, *H. elongata*, *H. halodenitrificans*, *H. marisflavi*, *H. muralis* and *H. salina*) are also moderately halophilic, but their optimum salinity for growth is lower (around 5%). In contrast to the previous group, most of these species show no requirement of salts or require only as little as 0.5%.

The slightly halophilic species (*H. desiderata*, *H. halocynthiae*, *H. magadiensis*, *H. meridiana*, *H. pacifica* and *H. venusta*) grow optimally at around 3% NaCl. However, these species are halotolerant of up to 20% NaCl (15% in the case of *H. halocynthiae*).

Carnimonas nigrificans shows only a limited level of halotolerance. For its isolation, two selective media have been proposed (Garriga et al., 1998), cetrimide agar and MacConkey agar, although it may grow in other media such as tryptone soy agar. Although the organism is not

Table 3. Physiological features of members of the family Halomonadaceae.

<i>Halomonas subglaciescola</i>	0.5–5–10–20	0–45	5.0–10.0
<i>Halomonas variabilis</i>	1–10–25	15–37	6.0–9.0
<i>Halomonas venusta</i>	0–0.5–7–20	4–45	5.0–10.0
<i>Zymobacter palmae</i>	nd	21–39	3.0–10.0

Abbreviation: nd, not determined.

pigmented, it produces black spots on the surface of cured meat products (the isolation source). This coloration seems to be the consequence of nonenzymatic reactions of substances derived from the meat surface.

Finally, *Zymobacter palmae* is neither halophilic nor halotolerant, but other special features of this organism can be used for its isolation. Thus, Okamoto et al. (1993) first selected for ethanol-tolerant bacteria using media with 5% (v/v) ethanol and then tested isolates for production of ethanol from maltose. *Zymobacter palmae* was found to produce ethanol from the fermentation of a variety of sugars: hexoses, α -linked di- and tri-saccharides, and sugar alcohols (fructose, galactose, glucose, mannose, maltose, melibiose, saccharose, raffinose, mannitol and sorbitol).

Regarding pH, most species are neutrophilic and therefore the pH of media can be adjusted to around 7.2–7.5. Exceptions to this rule are *H. campisalis*, *H. desiderata*, *H. magadiensis* and *H.*

pantelleriensis that grow optimally at pH 9.0 or 9.5 (Table 3).

Finally, although all halomonads are mesophilic, some differences in their behavior towards temperature can be used for selective isolation. *Chromohalobacter marismortui*, *C. salexigens*, *C. marina*, *H. desiderata*, *H. elongata*, *H. halophila* and *H. magadiensis* grew well at 37°C while the rest grew only suboptimally (or not at all). Temperatures around 28–30°C fit all known species so far. In the lower limit most species show no apparent growth below 4–10°C (20°C in the case of *H. magadiensis* and *Z. palmae*), but *H. subglaciescola* is capable of growing at 0°C (Table 3).

Preservation

A variety of media have been described for the routine maintenance of halomonads strains in

the laboratory. In many cases the same media served also for the isolation of the strains, whereas in others different formulations were employed. Some of these formulations, for instance the Artificial Organic Lake (AOL) medium of Franzmann et al. (1987), are intended to mimic the chemical composition of the environment from where the organisms are isolated. Once that isolation has been achieved many authors find it advantageous, especially if preparation of the isolation medium is too laborious, to employ a more general medium that permits the growth of both fresh isolates and reference strains. Thus, one of the most commonly employed media is MH, for moderately halophilic bacteria (Ventosa et al., 1982).

MH (Ventosa et al., 1982)

Yeast extract	10 g
Proteose peptone	5 g
Glucose	1 g
NaCl	81 g
MgCl ₂ · 6H ₂ O	7 g
MgSO ₄ · 7H ₂ O	9.6 g
CaCl ₂ · 2H ₂ O	0.36 g
KCl	2 g
NaHCO ₃	0.06 g
NaBr	0.026 g

Dissolve ingredients and q.s. to 1 liter with distilled water. Adjust pH to 7.2 with 1 M KOH or NaOH. Add agar (20 g liter⁻¹) for preparation of solid media. Adjust total saline content (commonly 10%) to any other desired value by lowering or raising proportionally the amounts of salts.

In a recent survey, Mata et al. (2002) employed MH medium at 7.5% salt content to maintain 104 *Halomonas* strains (including 21 type strains). For two of the strains, *H. magadiensis* NCIMB 13595^T and *H. campisalis* ATCC 700597^T, the pH was adjusted to 9.

For the species of the family Halomonadaceae with a lower salt requirement, commercial media such as Marine Agar (MA) can be satisfactorily employed (Yoon et al., 2001; Heyrman et al., 2002; Romanenko et al., 2002). Alternatively, other commercial media such as trypticase soy agar (TSA) can also be employed by adding NaCl (or a mixture of salts) or even no salts (for the nonhalophilic species).

Cultures on agar slants can be sealed and stored at 4–10°C. Although viability may last for much longer periods it is recommended that they be transferred regularly every 1–3 months.

For long-term preservation, lyophilization is advised. Prior to the vacuum drying, actively growing cells can be suspended on protecting fluids such as 5% inositol solution, and then the vials can be frozen by immersion into liquid nitrogen.

Cryopreservation at –80°C or under liquid nitrogen is also possible. To enhance survival of the cells they have to be suspended with a cryoprotectant such as 20% glycerol solution. Such prepared vials can also be stored at –20°C for middle-term preservation. However, since the quality of the culture may diminish faster (especially after frequent freeze-thawing) it is recommended that new stocks be prepared regularly.

Identification

The members of the family Halomonadaceae cannot be defined by a reasonably large number of common-to-all features. The phenotypic heterogeneity of the family is also a handicap for the identification at the genus or species level unless a sufficient number of characters are determined. Recently, Mata et al. (2002) reviewed in depth the phenotypic features of the genus *Halomonas*, including the type strains of the 21 species regarded at that time to be within the genus and 83 additional strains corresponding to four of these species to assess the intraspecies variability. They reported a large number of traits not analyzed previously for all strains and found tests that are useful for distinguishing the species of the genus *Halomonas*. These included tests for physiological traits (facultatively anaerobic growth, poly-β-hydroxybutyric acid accumulation, and production of exopolysaccharides), biochemical traits (hydrolysis of starch and casein, tyrosine pigment, respiration on nitrite, lysine decarboxylase, lecithinase, phenylalanine deaminase, growth on MacConkey agar, and hemolysis), nutritional traits (growth on succinate, L-alanine and L-serine), and antimicrobial susceptibility (i.e., susceptibility to nitrofurantoin, rifampicin and trimethoprim-sulfamethoxazole), as well as utilization of four of the substrates included in the Biolog GN2 system (*N*-acetyl-D-galactosamine, *p*-hydroxyphenylacetic acid, sebacic acid, and D-serine).

Sequence comparison of rRNA genes (16S and 23S) has proved to be a valuable tool for the taxonomic classification of this group (Dobson et al., 1993; Mellado et al., 1995b; Dobson and Franzmann, 1996; Arahall et al., 2002a), and in the same way, it is very useful for identification purposes. However, researchers have to be aware of the limitation of this method, especially at the species level (see Prokaryote Characterization and Identification in Volume 1), and therefore other approaches should not be neglected.

Given the large pool of 16S rRNA (and to a lesser extent 23S rRNA) sequences of the group,

the possibility of designing oligonucleotide probes for the in situ identification of halomonads is great, but unfortunately it has not been addressed yet.

The chemotaxonomy of the group was reviewed by Franzmann and Tindall (1990). The 16 strains included in that study represent 12 of the current species of the genus *Halomonas* plus *Cobetia* (*Halomonas*) *marina* and *Chromohalobacter salexigens* (*Halomonas elongata* DSM 3043). For most species described thereafter, the fatty acid profile is available whereas the analysis of menaquinones or polar lipids has been addressed for only a few of them. However, for identification purposes these chemotaxonomic markers are of limited value at the species level. Moreover, since the results are affected by the methodology employed and the culture conditions of the strains, a full comparison of different studies is not feasible.

The Subcommittee on the Taxonomy of the Halomonadaceae has discussed the need for a publication on minimal standards for describing new genera and species of the Halomonadaceae, and a working team is currently discussing the features and methods to be included.

The phenotypic features and the G+C content of species of the genera *Halomonas* (Table 4), *Chromohalobacter* and *Cobetia* (Table 5) and the genera of the family Halomonadaceae (Table 6) are shown below.

Physiology and Genetics

Osmoadaptation by some strains has been studied in more detail than any other physiological character. Osmoadaptation implies adaptation not only to a certain range of salinities but also to sudden changes in extracellular osmolarity. This is achieved thanks to a “salt-out” mechanism in which variable amounts of specific organic osmolytes are accumulated within the cytoplasm to balance the external osmotic pressure (Wohlfarth et al., 1990; Galinski, 1995; Kempf and Bremer, 1998; Vargas et al., 2004). The physiology of these (*Cobetia marina*, *H. alimentaria*, *H. campisalis*, *H. elongata*, *H. halodenitrificans*, *H. marisflavi*, *H. muralis* and *H. salina*) and other moderately halophilic bacteria has been extensively reviewed by Ventosa et al. (1998).

The species that exhibit a tolerance toward salts (which are the majority) usually depend upon a certain amount of NaCl in the environment for growth. For instance, *C. salexigens* requires at least 0.5 M NaCl in minimal medium (Cánovas et al., 1996). Recently, O'Connor and Csonka (2003) further characterized the ion requirements of *C. salexigens* and made the unexpected finding that while this organism

needs moderate concentrations of Na⁺ and Cl⁻ ions, its growth rate was stimulated by a number of other salts, indicating that *C. salexigens* requires a combination of NaCl and high ionic strength for optimal growth. However, *H. elongata* has a lower ionic requirement, and Cl⁻ can be substituted by other anions like Br⁻ or NO₃⁻, but not I⁻ or SO₄⁻² (Vreeland and Martin, 1980a). *Halomonas halophila* grows on NaBr, Na₂SO₄ and Na₂S₂O₃ as well as on NaCl but not on other sodium salts (Quesada et al., 1987). The role of K⁺ in osmoregulation of *H. elongata* was investigated by Kraegeloh and Kunte (2002). At lower salinities (0.51 M NaCl), K⁺ was the main cytoplasmic solute. At a double NaCl concentration, the same K⁺ content was measured, but this value was surpassed by the content of ectoine, the predominant cytoplasmic solute at higher salinity. Cells upon osmotic upshock were found to accumulate simultaneously ectoine and potassium glutamate, reaching levels greater than those found in cells adapted to high salinity (not stressed). The increase in K⁺ was long-lasting (more than 120 min) and not transient.

Chromohalobacter salexigens DSM 3043^T (previously *Halomonas elongata* DSM 3043; Arahal et al., 2001b) and *H. elongata* DSM 2581^T have been used as model organisms for a large number of osmoadaptation studies in moderate halophiles that have been reviewed recently by Ventosa et al. (1998), Kunte (2004) and Vargas et al. (2004).

Many of the osmoadaptation mechanisms of *C. salexigens* and *H. elongata* are now understood at the molecular level (Kunte, 2004; Vargas et al., 2004). When present in the extracellular environment, *C. salexigens* is able to take up ectoine, hydroxyectoine, betaine, choline, and choline-O-sulfate. At least three transport systems have been inferred. Into the cell, choline is oxidized to betaine and the genes involved—*betIBA* genes—have been cloned and characterized (Cánovas et al., 1998b; Cánovas et al., 2000). In *H. elongata*, Grammann et al. (2002) have described the isolation and molecular characterization of an osmoregulated transport system—TeaABC—showing high affinity for ectoine and hydroxyectoine.

When grown in a minimal medium, *C. salexigens* synthesizes de novo the compatible solutes ectoine and its derivative hydroxyectoine. The sequences of the genes involved in the synthesis of ectoine—*ectABC*—were isolated and characterized (Cánovas et al., 1998a). They code for a diaminobutyric acid acetyltransferase, a diaminobutyric acid aminotransaminase, and an ectoine synthase, respectively (Table 7). The *C. salexigens* EctA, EctB and EctC genes showed the same organization as well as a significant degree of sequence identity to the genes of

ectoine synthesis in *H. elongata* (Göller et al., 1998), *Marinococcus halophilus* (Louis and Galinski, 1997) and *Sporosarcina pasteurii* (Kuhlmann and Bremer, 2002). Thus, it seems that the ectoine biosynthetic route, which was first elucidated at the biochemical level in the closely related *H. elongata* (Peters et al., 1990; Ono et al., 1999), is evolutionarily well conserved in all ectoine-producing bacteria characterized so far. Very recently, Calderón et al. (2004) investigated the long-term regulation of ectoine synthesis in *C. salexigens*, with emphasis in the transcriptional regulation, and found preliminary indications of great complexity of this process. S1 protection analyses performed with RNA extracted from cells grown in minimal medium at low (0.75 M NaCl) or high (2.5 M NaCl) osmolarity suggested

the existence of four promoters upstream of *ectA*. Two of these (*PectA1* and *PectA2*) might be recognized by the main vegetative sigma factor σ^{70} , and one (*PectA3*) might be dependent on the general stress factor σ^S . The S1 protection assays suggested that *PectA1* and *PectA3* may be osmoregulated promoters. In addition, an internal promoter showing sequences homologous to promoters dependent on the heat-shock sigma factor σ^{32} was found upstream of *ectB*. Transcription from *PectA* in *C. salexigens* followed a pattern typical of σ^S -dependent promoters, and was reduced by 50% in an *Escherichia coli* *rpoS* background. These data strongly suggest the involvement of the general stress factor σ^S in *ectABC* transcription in *C. salexigens*. Expression of *PectA-lacZ* and *PectB-lacZ* transcriptional

ulated in cells grown with an excess of iron (FeCl₃). Table 7 shows other genes from members of the family Halomonadaceae that have been sequenced and characterized.

Estimations of the genome size of eleven *Halomonas* and *Chromohalobacter* strains by using pulsed-field gel electrophoresis are in the range 1.5–2.8 Mb (Mellado et al., 1998). The genome size of *H. eurihalina* F2-7 has been determined recently as 2.5 Mb, together with its topology and a preliminary physical map (Llamas et al., 2002). The type strain of *H. maura* has a larger chromosome (3.5 Mb; Quesada et al., 2004). A summary of estimations of the genome size of some halomonads is presented in Table 8.

Although research on the nonhalophilic species of the family Halomonadaceae is less abundant, some studies have been conducted. Thus, the pyruvate decarboxylase gene, *pdh*, of *Z. palmarum* has been cloned and characterized (Raj et al., 2002). Its product is the key enzyme in all homo-ethanol fermentations, and so far it has only been identified in three other bacteria. Among eukaryotes, it is absent in animals but widely distributed in plants, yeasts and fungi.

The presence of plasmids (and megaplasmids) in strains of *Halomonas*, *Chromohalobacter* and *Cobetia* has been investigated (Table 9). Plasmid pHE1 (from *C. salexigens* ATCC 33174) was selected for its small size (4.2 kb) and served for the construction of a shuttle vector, pHS15, for related moderately halophilic bacteria (Vargas et al., 1995). The mobilization (*mob*) region of plasmid pHE1 has been characterized revealing the presence of four open reading frames (Vargas et al., 1999). In the same way, plasmids pEE3 and pEE5 are derivatives of plasmid pCM1 from *C. marismortui* (Mellado et al., 1995c). More recently, Argandoña et al. (2003) have discovered that many Halomonadaceae strains

harbor large extrachromosomal DNA elements, although they are technically very difficult to identify by using standard protocols. Under appropriate culture conditions and applying a modified gel electrophoresis method, they found that almost all species studied harbor two plasmids of about 70 kb and 600 kb, and some species carry other smaller extrachromosomal DNA elements (Table 9).

Ecology

It can be inferred that halomonads are very ubiquitous and versatile chemoheterotrophic microorganisms from the variety of habitats they are found in (Table 2) and from their phenotypic heterogeneity (Mata et al., 2002). Studies on the ecology of hypersaline habitats are of particular interest because of their reduced diversity with increasing salinity. When the community of moderately halophilic bacteria is analyzed by numerical taxonomy approaches in salt lakes and brines, halomonads (or halomonad-like) strains are commonly isolated (Ventosa et al., 1998). However, such classical studies have been lately surpassed by molecular techniques or a combination of both.

Information derived from publicly available 16S rRNA sequences reveals that both isolates and environmental clones are being isolated from a wide range of environments, such as continental shelf sediments collected off Antarctica, deep-sea sediment from Pacific Ocean, Great Salt Plains of Oklahoma, Lake Texcoco (Mexico), the Hawaiian Archipelago, tropical ecosystems, or the Arctic Sea, to name a few. They are present in bulk water, oxic and anoxic transition zones, and anoxic basins or sediments at almost any range of salinities and a wide range of pH and temperature.

Most probable number (MPN) estimates of halotolerant microorganisms in hydrothermal-vent and pelagic waters of the North and South Pacific showed that up to 28% of the total microbial community was halotolerant. Fourteen isolates from these MPN enrichments

were identified by comparison of partial 16S rRNA gene sequences, and eight were found to belong to the genus *Halomonas* (Kaye et al., 2000).

Halomonads have also been found during the characterization of microbial assemblages asso-

ciated with high-temperature petroleum reservoirs (Orphan et al., 2000). Indeed, they represented the main group (9.4%) of a clone library generated from total community DNA collected from production wellheads (mean depth 1700 m below the sea floor) in California using universally conserved 16S rRNA-targeted polymerase chain reaction primers. The closest relatives to the halomonads phylotypes were *H. variabilis* (20 clones, 16S rRNA similarity range 98.5–99.6%) and *H. pacifica* (one clone, 16S rRNA similarity 97.2%).

A recent study has been conducted on the microbial communities from a subsea floor sediment core from the southwestern Sea of Okhotsk by cultivation-independent and cultivation-dependent analyses (Inagaki et al., 2003). Of 322 bacterial 16S rRNA clones, 264 (82.0%) grouped with Gammaproteobacteria, and among them, the predominant groups belonged to the genera *Halomonas*, *Methylophaga* and *Psychrobacter*. The *Halomonas* relatives included 147 clones (45.7%), of which two large groups were closely related to *H. variabilis* and *H. meridiana*. With respect to the isolates (181 strains selected on the basis of colony morphology, sample depth and cultivation conditions), the Gammaproteobacteria were again the main group (93.3% of isolates). Moreover, the most predominant colony phylotype accounted for 82 isolates (45.3%) and exhibited around 98% 16S rRNA sequence similarity with *H. variabilis*.

Disease

Members of the Halomonadaceae are not pathogenic. There is one case report on the isolation of *H. venusta* from a human infection in a wound that originated from a fish bite (Von Graevenitz et al., 2000); however the identification of the organism alone does not prove its pathogenicity.

Applications

The species of the Halomonadaceae can be used for several biotechnological purposes and, as in the case of other extremophilic microorganisms, many different applications have been suggested. The biotechnological potential and applications of moderately and halotolerant microorganisms have been reviewed in detail recently (Ventosa et al., 1998; Margesin and Schinner, 2001; Mellado and Ventosa, 2003). Some of the most promising applications of members of Halomonadaceae include the production of compatible solutes as well as extracellular compounds such as exopolysaccharides and enzymes, and their use in environmental bioremediation processes.

Compatible solutes are known for their stabilizing and protective effect on enzymes, nucleic acids, cell structures or whole cells subjected to low water activities, temperature stress, and other adverse conditions (Lippert and Galinski, 1992; Galinski, 1993; Knapp et al., 1999). A “bacterial milking” process to obtain ectoine from *Halomonas elongata* has been developed and patented (Sauer and Galinski, 1998) and later industrially exploited by Bitop (Witten, Germany). The process is based on subjecting the bacteria repeatedly to osmotic shocks. An osmotic down-shock permits the excretion of the intracellular ectoine to the surrounding medium while subsequent exposure of the cells to a hyperosmotic shock quickly restores the original level of ectoine (Sauer and Galinski, 1998). Ectoine and its derivative hydroxyectoine are used in the cosmetic industry because of their moisturizing properties. The potential use of the *C. salexigens* and *H. elongata* *ect* genes (responsible for the synthesis of ectoine) to obtain agriculturally important transgenic organisms tolerant to osmotic stress has already been proposed (Vargas et al., 2004). Nakayama et al. (2000) obtained transgenic cultured tobacco cells that accumulated the compatible solute ectoine from *H. elongata*, exhibiting a normal growth pattern under hyperosmotic conditions.

Strains from several species of *Halomonas* are of interest as producers of exopolysaccharides (EPS). These include *H. maura*, *H. eurihalina*, *H. salina* and *H. halophila* (Quesada et al., 2004), as well as other recent isolates that may represent new *Halomonas* species (E. Quesada et al., personal communication). The nutritional and environmental factors influencing the production of EPS have been thoroughly investigated by Quesada and coworkers (Quesada et al., 1993; Béjar et al., 1996; Béjar et al., 1998; Bouchotroch et al., 1999; Bouchotroch et al., 2000; Martínez-Checa et al., 2002). Yield can reach 1–3 g of EPS per liter of medium after five days of cultivation. Glucose and sucrose are the most efficient carbon sources (Béjar et al., 1996) although many other nutrients can be used including end products such as molasses from sugar beet (Quesada et al., 2004). Production of the EPS is not inhibited by the presence of crude oil. Moreover, the composition of the biopolymer is different under such conditions showing a highly efficient emulsifying activity towards crude oil (Calvo et al., 2002). Interestingly, it has been observed that strains of *H. maura* and *H. eurihalina* produce more EPS at salt concentrations below 7.5% (w/v), which are suboptimal for growth (Quesada et al., 1993; Bouchotroch et al., 2000). As for the chemical composition of the EPSs produced from *Halomonas* strains, they are anionic poly-

mers composed mainly of carbohydrates and a minor fraction of proteins, uronic acids and acetyls. Sulfate substituents have also been detected (in some strains exceeding 20% of the dry weight), and together with the uronic acids, make the EPS anionic. Depending on their composition EPSs have different functional properties and thus different applications, which include immunomodulation, biotransformation of heavy-metal polluted environments, crude oil emulsification, viscosity enhancement in foods, among others (Quesada et al., 2004). The properties of some of these EPSs such as maura, H28 or V2-7 have been studied in detail highlighting in each case their biotechnological potentials (Pérez-Fernández et al., 2000; Martínez-Checa et al., 2002; Arias et al., 2003).

Another interesting field is the production of extracellular enzymes (i.e., amylases, proteases and nucleases) by moderately halophilic representatives of the family. Although few studies have been carried out, this is a promising subject that has been reviewed very recently (Mellado et al., 2004). Sánchez-Porro et al. (2003) studied the diversity of moderately halophilic bacteria able to produce several extracellular hydrolytic enzymes (amylases, DNases, lipases, proteases and pullulanases) by screening different hypersaline locations in South Spain. In contrast to the scarce hydrolytic activity shown by culture collection strains, environmental isolates produce a variety of extracellular enzymes that could be of potential biotechnological interest. Identification at the genus level revealed that 25 strains and 2 out of 122 isolates belonged to *Halomonas* and *Chromohalobacter*, respectively. An α -amylase produced by *Halomonas meridiana* has been studied at the biochemical and molecular level (Coronado et al., 2000a; Coronado et al., 2000b). The amylase showed optimal activity at 10% NaCl, 37°C and pH 7.0 (being relatively stable under alkaline conditions). The enzyme showed activity at high salt concentrations (up to 30%). The main products resulting from the hydrolysis of starch were maltose and maltotriose. The gene encoding this α -amylase (*amyH*) has been cloned and expressed in the heterologous hosts *H. elongata* and the non-halophilic bacterium *E. coli* (Coronado et al., 2000b). It encodes a 457-residue protein with a molecular mass of 50 kDa. Besides, an extracellular α -amylase gene from the hyperthermophilic archaeon *Pyrococcus woesei* has been cloned and expressed in *H. elongata*, under the control of a native *H. elongata* promoter (Frillings et al., 2000).

Halomonads and other moderately halophilic bacteria can be also used for the degradation of toxic compounds both at high and intermediate salt concentrations, permitting the restoration of saline industrial residues and contaminated

saline environments (Mellado and Ventosa, 2003). However, few studies have been carried out. Some examples of halomonads with a potential for biodegradation and biotransformation of contaminants (such as aminomethane sulfonate, organophosphonates, benzoate, formaldehyde, phenol, selenate and uranium compounds) are shown in Table 7. Maltseva et al. (1996) isolated halomonads able to use chloroaromatic compounds as the sole source of carbon and energy and studied in detail the degradation of the herbicide 2,4-dichlorophenoxyacetic acid (2,4-D). Kleinstaub et al. (2001) reported the use of the alkaliphilic, moderately halophilic *Halomonas* sp. strain EF43 for the expression of the 2,4-D-degradative pathway by conjugation of the broad host range plasmid pJP4. This strain was able to degrade 2,4-D- and 3-chlorobenzoate under alkaline conditions in the presence of an additional carbon source.

Very recently, a screening of moderately halophilic bacteria able to use aromatic compounds permitted the isolation of a large number of members of the genus *Halomonas* able to degrade different compounds. Some of them may represent new species of *Halomonas*, such as "*H. organivorans*," which is able to use benzoic acid, *p*-hydroxybenzoic acid, cinnamic acid, salicylic acid, phenylacetic acid, phenylpropionic acid, phenol, *p*-coumaric acid, ferulic acid and *p*-aminosalicylic acid (M. T. García et al., personal communication). The tolerance patterns of several *Halomonas* species and *Chromohalobacter marismortui* to ten heavy metals have been studied, as well as the influence of salinity and composition of culture media (Nieto et al., 1989). These studies may be interesting for future use of metal-tolerant halophilic strains as biological detoxicants.

Few studies have been carried out on the role of halomonads in the fermentation processes of foods and other products. *Halomonas alimentaria* was isolated from the traditional Korean fermented seafood jeotgal (Yoon et al., 2002). The hydrolytic activity of *H. elongata* in bacon curing brines has been investigated (Hinrichsen et al., 1994).

Fuel ethanol production has been proposed using the pyruvate decarboxylase (PDC) of *Z. palmae* as biocatalyst (Raj et al., 2002). This enzyme is thermostable and showed the highest specific activity and lowest K_m for pyruvate of all four known bacterial PDCs.

Acknowledgments. We thank Prof. K.-H. Schleifer and Dr. C. Vargas for the critical reading of the manuscript. We also acknowledge the financial support from the Spanish Ministerio de Ciencia y Tecnología (BMC2003-1344), the

Quality of Life and Management of Living Resources Programme of the European Commission (QLK3-CT-2002-01972), and Junta de Andalucía. D. R. A. has a contract with the Universitat de València under the Ramón y Cajal program (Spanish Ministerio de Ciencia y Tecnología).

The Genus *Deleya*

KAREL KERSTERS

The genus *Deleya*, along with the genus *Halomonas*, comprises the family Halomonadaceae (Franzmann et al., 1988). This family encompasses various halotolerant and moderately halophilic rod-like Gram-negative nonfermentative, chemoorganotrophs that require 75 mM to 200 mM NaCl for growth. However, some *Deleya* strains grow optimally only in media containing at least 7.5% salts (1.3 M NaCl). “Salt-loving” is a universal feature of all strains belonging to the genera *Deleya* and *Halomonas*, and *Deleya* strains have been isolated from marine environments, solar salterns, saline soils, and salted food.

Within the Proteobacteria, the family Halomonadaceae belongs to the rRNA superfamily II sensu De Ley (1978) (see The Proteobacteria: Ribosomal RNA Cistron Similarities and Bacterial Taxonomy in the second edition), i.e., part of the gamma subclass sensu Stackebrandt et al. (1988). The genus *Deleya* consists of six validly published species: *D. aesta*, *D. cupida*, *D. halophila*, *D. marina*, *D. pacifica*, and *D. venusta* (Baumann et al., 1983; Quesada et al., 1984). The genus is both genotypically and phenotypically heterogeneous; the GC content of the DNA ranges from 52 to 68 mol%. Good evidence exists (see below) that these six *Deleya* species, together with the *Halomonas* species, are part of a single evolutionary lineage. DNA-rRNA hybridizations (De Vos et al., 1989, and this chapter) and chemotaxonomic analyses (Akagawa and Yamasato, 1989; Franzmann and Tindall, 1990) revealed that various organisms misnamed as members of the genera *Pseudomonas*, *Alcaligenes*, and *Achromobacter* are authentic members of the genus *Deleya*. In the text below, misnamed taxa are enclosed by brackets, [], and invalid taxon names are in quotation marks, “ ”.

Intra- and Suprageneric Relationships of *Deleya* Species and Allied Bacteria

In a taxonomic study of more than 200 Gram-negative, nonfermentative, marine eubacterial

strains, Baumann et al. (1972) assigned peritrichously flagellated strains of four different phenotypes to four new species of the genus *Alcaligenes* ([*A.*] *aestus*, [*A.*] *cupidus*, [*A.*] *pacificus*, and [*A.*] *venustus*, respectively). Hendrie et al. (1974) considered [*Achromobacter*] *aquamarinus* (ZoBell and Upham, 1944) as an acceptable species within the genus *Alcaligenes*. However, it is now well established that all these marine [*Alcaligenes*] strains are genotypically and phenotypically very different from the type species *Alcaligenes faecalis*. The latter species belongs, together with some other *Alcaligenes* taxa and all *Bordetella* species, in the family Alcaligenaceae (De Ley et al., 1986) within the rRNA superfamily III (beta subclass) of the Proteobacteria (see also The Proteobacteria: Ribosomal RNA Cistron Similarities and Bacterial Taxonomy in the second edition). On the other hand, all marine [*Alcaligenes*] species are members of the rRNA superfamily II (part of the gamma subclass) (De Ley, 1978; Kersters and De Ley, 1980) and are phylogenetically more related to the authentic *Pseudomonas* species (i.e., *Pseudomonas* section I of Palleroni, 1984). In *Bergey's Manual of Systematic Bacteriology*, the marine [*Alcaligenes*] species were therefore considered as species incertae sedis (Kersters and De Ley, 1984). Evolutionary studies on pathways of carbohydrate metabolism (Sawyer et al., 1977) and on patterns of regulation of aspartokinase activities (Baumann and Baumann, 1974), immunological studies on superoxide dismutases and glutamine synthetases (Baumann and Baumann, 1978; DeLong et al., 1984) as well as chemotaxonomic data (Akagawa and Yamasato, 1989; Franzmann and Tindall, 1990), also yielded strong evidence that the peritrichously flagellated marine [*Alcaligenes*] species constitute a single evolutionary lineage, together with the polarly flagellated species [*Pseudomonas*] *marina*. This group of bacteria is unrelated to the authentic *Alcaligenes* species and is also distinct from the fluorescent pseudomonads, which are their close relatives. On the basis of all these arguments Baumann et al. (1983) proposed a new genus called *Deleya* to accommodate the marine [*Alcaligenes*] species together with [*P.*] *marina*. *D. halophila* was described by Quesada et al. (1984) for strains isolated from hypersaline soils in Spain. On the

basis of cellular fatty acid profiles, biochemical and physiological features and DNA-DNA hybridizations, Akagawa and Yamasato (1989) proposed that [*Alcaligenes*] *aquamarinus* was synonymous with *Deleya aesta* and *Deleya aquamarina* be recognized as the type species of the genus *Deleya*. DNA-rRNA hybridizations were performed in order to unravel the inter- and intragenetic relationships of the species of the genus *Deleya*. Fig. 1 summarizes our present knowledge of the position of various taxa and strains on the *Deleya* rRNA branch. All hybridizations were carried out versus labeled rRNA of *Deleya aquamarina* NCMB 557^T (the former [*Alcaligenes*] *aquamarinus*). The branching point of the genus *Halomonas* at a Tm(e) value of 76°C agrees very well with data from 16S rRNA cataloging (Franzmann et al., 1988). With the latter method, four halophilic species, *Halomonas elongata*, *H. subglaciescola*, *H. halmophila* (ex [*Flavobacterium*] *halmophilum*; Franzmann et al., 1988) and *D. aesta*, form a fairly coherent cluster phylogenetically, with a lowest branching at S_{AB} 0.60 (Franzmann et al., 1988). In the Tm(e) dendrograms, the family Halomonadaceae at 70°C is closest to the authentic *Pseudomonas* group and to *Marinomonas* (Fig. 1).

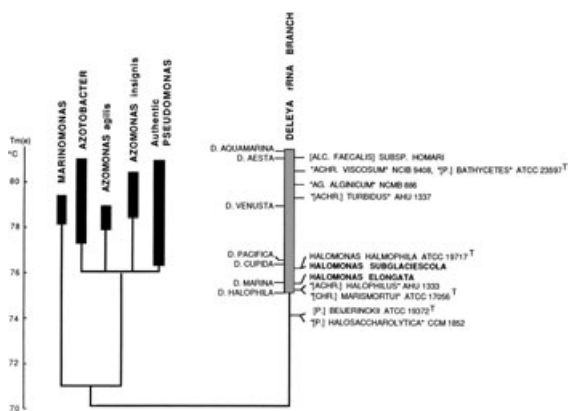

Fig. 1. Simplified rRNA cistron-similarity dendrogram of *Deleya* and related taxa. Tm(e) is the temperature at which 50% of the DNA-rRNA hybrid is eluted. The black bars at the top of the branches represent the ranges of the Tm(e) values of the reference taxa. The position of all validly published *Deleya* species is indicated at the left side of the *Deleya* rRNA branch, whereas three species of *Halomonas* and various generically misnamed taxa and strains are on the right side of this rRNA branch. Abbreviations: ACHR., *Achromobacter*; AG., "*Agarbacterium*"; ALC., *Alcaligenes*; CHR., *Chromobacterium*; D., *Deleya*; F., *Flavobacterium*; P., *Pseudomonas*. The position of this group of bacteria within rRNA superfamily II (part of the gamma subclass) of the Proteobacteria can be found in Fig. 5 of The Proteobacteria: Ribosomal RNA Cistron Similarities and Bacterial Taxonomy in the second edition. Tm(e) values were taken from De Vos and De Ley (1983), De Vos et al. (1989), Van Landschoot and De Ley (1983), and P. Segers (unpublished observations).

On the basis of Tm(e) values of DNA-rRNA hybrids versus *D. aquamarina* NCMB 557^T, two groups of strains can be recognized on the *Deleya* rRNA branch (Fig. 1):

1. Strains located in the top 3°C ΔTm(e), including *D. aquamarina* (the type species), *D. aesta* (synonym of *D. aquamarina*), *D. venusta*, [*A. faecalis*] subsp. *homari* isolated from lobsters, "[P.] bathycetes" "*Agarbacterium alginicum*," and some misnamed *Achromobacter* strains; all these strains possess DNA with a GC content of 52–61 mol%. Akagawa and Yamasato (1989) found that [*A. faecalis*] subsp. *homari* is highly similar to *D. aquamarina*. When more data on their phenotype and genotype will be available, the other misnamed strains will very likely be allocated to the genus *Deleya* either as synonyms of existing species or as separate species.

2. Strains located at the bottom 5–7°C ΔTm(e), including *D. cupida*, *D. halophila*, *D. marina*, *D. pacifica*, *H. elongata* (type species of the genus *Halomonas*), *H. subglaciescola*, and various misnamed strains (see Fig. 1); the GC content of their DNA ranges from 59 to 68 mol%. More detailed rRNA comparisons are required to elucidate the exact relationships between the different members of this group. In particular, the relationships among this group of strains and all members of the genus *Halomonas* need to be investigated.

Generically Misnamed Taxa and Strains of the *Deleya* rRNA Branch

Genomic and phenotypic studies have indicated that a great number of generically misnamed taxa and strains are authentic members of the *Deleya* rRNA branch (P. Segers and K. Kersters, unpublished observations). The position of these taxa and individual strains is indicated in Fig. 1; additional information on the habitats of these organisms can be found in Table 1.

"[*Pseudomonas*] *bathycetes*" originates from deep-sea sediments (Quigley and Colwell, 1968); "*Agarbacterium alginicum*" was isolated from the surface of brown algae and [*Alcaligenes faecalis*] subsp. *homari* is pathogenic for lobsters (Austin et al., 1981). The immunological data of DeLong et al. (1984) on glutamine synthetases indicate that [*Alcaligenes faecalis*] subsp. *homari* is not related to *Alcaligenes*, but it is highly similar to *Deleya*. DNA-rRNA hybridizations (Fig. 1) show that these taxa, together with strains "[*Achr.*] *viscosum*" NCIB 9408 and "[*Achr.*] *turbidus*" AHU 1337, belong to the genus *Deleya*. Some misnamed [*Pseudomonas*] and [*Achromobacter*] strains were isolated from salted food, whereas "[*Chromobacterium*] *marismortui*" originates from water of the Dead Sea.

Table 1. Sources and geographical distribution of taxa and strains belonging to the *Deleya* rRNA branch.

Species or strain ^a	Source of isolation	Geographical origin	Reference
<i>Deleya aesta</i>	Seawater (at 100–600 m deep)	Hawaii, USA	Baumann et al. (1972)

Intragenetic Relationships of Species of *Deleya*

Data on the finer internal taxonomic relationships of the genus *Deleya* are scarce. Most of the well-established *Deleya* species have been delineated on the basis of numerical taxonomic studies of phenotypic features (Baumann et al., 1972; Marquez et al., 1987; Quesada et al., 1983). DNA-DNA hybridizations revealed that the following taxa are highly related (more than 75% homology): *D. aesta*, *D. aquamarina*, the lobster isolates (*[A. faecalis]* subsp. *homari*), and “*[Achromobacter]* *viscosum*” strain NCIB 9408 (P. Segers and B. Hoste, unpublished observations). They are all located in the top 1°C ΔT_m(e) of the *Deleya* rRNA branch (Fig. 1), and the GC content of their DNA ranges from 57 to 61 mol%. No significant DNA homologies were detected between *D. aquamarina* and the type strains of the other *Deleya* species (Akagawa and Yamasato, 1989).

Habitats

One common characteristic of all the strains belonging to the *Deleya* rRNA branch is their isolation from salt-containing materials. Table 1 gives an overview of the various habitats where strains of the *Deleya* rRNA branch have been found. Many *Deleya* strains are from marine origin and grow optimally at salt concentrations of 0.4% to 1.2% NaCl (Baumann et al., 1983), but others such as *D. halophila* are moderate halophiles because they display optimal growth at 7.5% NaCl (Ferrer et al., 1987). *D. halophila* strains were usually isolated from hypersaline soils and solar salterns (Quesada et al., 1982; 1983). *Deleya* strains have also been isolated from ponds of an inland Spanish saltern which was supplied with water from a subterranean inland saline well (del Moral et al., 1987, 1988).

Some strains—previously assigned to the ill-defined genus *Achromobacter*—were isolated from various salt-containing foods (Table 1). Austin et al. 1981 isolated *[Alcaligenes faecalis]* subsp. *homari* strains from the hemolymph of moribund and dead lobsters. These lobsters were reared in tanks containing seawater; their death occurred after the water in the tanks accidentally reached a temperature of 26°C for three days. The isolated bacteria were found to be pathogenic for lobsters. It has been proven (see above) that three of these isolates (including the type strain) were phenotypically and genomically highly related to *D. aesta* (type species) and *D. aquamarina* (Fig. 1).

Isolation

The following media and isolation procedures were used by several authors for the isolation of

strains belonging to the *Deleya* rRNA branch. More details can be found in Baumann and Baumann (1981).

Media For the Isolation of *Deleya* Species

Artificial Seawater (ASW) (MacLeod, 1968)

NaCl	400 mM
MgSO ₄ · 7H ₂ O	100 mM
KCl	20 mM
CaCl ₂ · 2H ₂ O	20 mM

Dissolve the salts separately in distilled water and combine.

Basal Medium (BM)

TrisHCl (pH 7.5)	50 or 100 mM
NH ₄ Cl	19 mM
K ₂ HPO ₄ · 3H ₂ O	0.33 mM
FeSO ₄ · 7H ₂ O	0.1 mM
Half-strength ASW	

The carbon source is usually supplied at a concentration of 0.1–0.2% (w/v for solids and v/v for liquids). Labile compounds should be filter-sterilized.

Basal Medium Agar (BMA)

Prepare equal volumes of double-strength BM and double-strength agar in distilled water (40 g agar per liter), sterilize by autoclaving, and combine before pouring on plates. Carbon and energy sources can be added to double-strength BM prior to autoclaving. Labile compounds should be filter-sterilized and added to BMA, which has been cooled to about 42°C prior to pouring on plates.

Marine Agar (MA)

Marine agar 2216E is available from Difco Laboratories, Detroit, Mich., USA.

Medium for Moderately Halophilic Bacteria (MH Medium) (Quesada et al., 1983)

5 g proteose peptone, 10 g yeast extract, and 1 g glucose are dissolved in 10% (w/v) marine salts solution. Marine salts solution contains, in one liter of distilled water:

NaCl	81 g
MgCl ₂ · 6H ₂ O	7 g
MgSO ₄ · 7H ₂ O	9.6 g
CaCl ₂ · 2H ₂ O	0.36 g
KCl	2 g
NaHCO ₃	0.06 g
NaBr	0.026 g

The pH is adjusted to 7.2 with 1 M KOH, and agar (20 g/liter) is added.

MH medium with e.g., 20% marine salts, is prepared by doubling the amount of inorganic salts in the above medium. Lowering the concentration of Mg²⁺ (to 1 g MgSO₄ · 7H₂O/liter) increases the selectivity of the MH medium for moderate halophiles, because growth of extreme halophiles is suppressed (Marquez et al., 1987).

Isolation Procedures

ISOLATION FROM SEAWATER (BAUMANN ET AL., 1972) The enrichment culture methods have been described by Baumann et al. (1971) and Baumann and Baumann (1981). Various amino

acids (L-lysine, L-glutamate, L-histidine), amines (e.g., histamine) and organic acids (glycolate, *o*-hydroxybenzoate) have been used as sole carbon source for enrichment of *Deleya* strains (Baumann et al., 1972). The strains are purified on BMA containing 0.1% of the same carbon compound as used in the enrichment, or on BMA containing 0.1% Na succinate, 0.1% Na lactate and 0.1% Na acetate.

For direct isolation, samples of sea water are filtered through 0.22- or 0.45- μ m pore size nitrocellulose filters, which are placed in petri dishes containing Marine Agar or Basal Medium Agar with 0.1% organic substrates (e.g., *meso*-inositol, D-galactose, adipate, L-valine, etc.) (Baumann et al., 1972).

ISOLATION FROM HYPERSALINE SOILS (QUESADA ET AL., 1983, 1984) *D. halophila* was isolated from hypersaline soils in Spain by suspending one soil sample in 10 ml of 10% marine salts solution (see above); 10-fold dilutions were made (always keeping the same balanced salt concentrations), and 0.1 ml of each dilution was plated on MH medium.

ISOLATION FROM THE HEMOLYMPH OF LOBSTERS (AUSTIN ET AL., 1981) Drops of aseptically collected hemolymph from moribund lobsters (*Homarus americanus*) were inoculated on Marine Agar medium for the isolation of [*Alcaligenes faecalis*] subsp. *homari*. Plates were incubated at 19°C for 7 days.

PRESERVATION OF CULTURES Baumann and Baumann (1981) recommended maintenance of *Deleya* strains on MA slants. After each monthly transfer, cultures were allowed to grow at 25°C for 1–2 days and stored at 18°C. Quesada et al. (1983) maintained their strains on slants of MH medium. We maintained *Deleya* strains at 4°C on slants of the following medium: 1% peptone, 0.8% beef extract powder, 3% NaCl, and agar in tap water. Lyophilization is recommended for long-term preservation.

Identification

The range of GC content of the DNAs of members of the genus *Deleya* is very broad (52–68 mol%) and is reflected in 1) the fairly great span of $\Delta T_m(e)$ values of their DNA-rRNA hybrids versus labeled rRNA of *D. aquamarina* (see Fig. 1); and 2) considerable phenotypic and genotypic heterogeneity within the genus. An important common feature for all *Deleya* species is their absolute requirement for at least 75–200 mM NaCl for optimal growth. This feature differentiates *Deleya* from terrestrial *Pseudo-*

monas and *Alcaligenes* species (Baumann and Baumann, 1981).

Deleya species can be differentiated from other marine eubacteria by four important features: absence of fermentation of D-glucose, accumulation of poly- β -hydroxybutyrate, peritrichously flagellated cells (except *D. marina*), and by the parameters of their DNA-rRNA hybrids. Differentiation of *Deleya* from *Halomonas* species is difficult because no comprehensive phenotypic or genomic studies have been performed using standardized procedures. Species of *Deleya* can best be differentiated from each other by carbon assimilation tests (Table 2).

Deleya strains are Gram-negative straight rods, 0.8 to 1.1 μ m wide and 1.5 to 3.0 μ m long. They accumulate poly- β -hydroxybutyrate as an intracellular reserve product. Involution forms may occur in old cultures or under adverse conditions of cultivation. Endospores are not formed. Motile by four to twelve peritrichous flagella, except *D. marina* which is motile by two to five polar flagella. They are obligately aerobic, possessing a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Colonies are nonpigmented. They do not denitrify or fix molecular nitrogen and do not grow chemolithotrophically with hydrogen gas and CO₂. All species are chemoorganotrophs able to grow on a mineral medium containing sea water base, D-glucose and NH₄Cl. Na⁺ is an absolute requirement for all species; the minimal concentration for optimal growth ranges from 75 to 200 mM (or even 1.3 M for *D. halophila*). All species utilize acetate, succinate, DL- β -hydroxybutyrate, DL-lactate, glycerol, and L- α -alanine. All *Deleya* (and *Halomonas*) strains contain ubiquinone 9 as the major respiratory quinone with traces of Q8, and 16:1 *cis* 9, 16:0, 17:0 cyclo, 18:1 and 19:1 cyclo 11–12 as major fatty acids (Franzmann and Tindall, 1990). The GC content of the DNA ranges from 52 to 68 mol%. The type species is *D. aquamarina* (type strain ATCC 14400, NCMB 557, DSM 30161, LMG 2853, IAM 12550).

Table 2 lists the diagnostic features for the differentiation of species of the genus *Deleya*. The original publications should be consulted for full descriptions (see references in footnotes of Table 2). The type strains of the species are also listed at the bottom of Table 2. Akagawa and Yamasato (1989) give a few other biochemical and physiological features to differentiate the type strains of the *Deleya* species.

Physiological Properties

Species of *Deleya* have no organic growth factor requirements and utilize a great variety of organic compounds as sole sources of carbon and

energy. They can assimilate pentoses, hexoses, disaccharides, sugar alcohols, sugar acids, fatty acids, dicarboxylic acids, tricarboxylic acid cycle intermediates, amino acids, amines, and some aromatic substances. The latter compounds are metabolized via the β -ketoadipate pathway involving the *ortho*-cleavage of diphenolic compounds (Baumann et al., 1972). D-Glucose and D-fructose are metabolized via the Entner-Doudoroff pathway (Baumann and Baumann, 1973; De Ley et al., 1970; Sawyer et al., 1977).

Growth characteristics of the type strain of *Deleya halophila* have been studied in more detail by the research group of A. Ramos-Cormenzana. *D. halophila* displays a specific requirement for Na^+ , which cannot be replaced by other cations (Quesada et al., 1987). Optimal growth of *D. halophila* occurs at 7.5% total salts, when incubated at 32 or 42°C. However, when the incubation temperature is lowered to 22°C, its optimal growth occurs at 5% total salts. *D. halophila* is able to grow at salt concentrations varying from 2.5% to 25% (Ferrer et al., 1987). Such characteristics are typical of moderately halophilic bacteria isolated from hypersaline soils, where salt content can vary considerably in space and time.

Investigations have been performed on the effects of growth temperature and salt concentration on the cellular fatty acid composition of *D. halophila*, "[*Pseudomonas*] *halosaccharolytica*," and *Halomonas halmophila* (ex [*Flavobacterium*] *halmophilum*; Franzmann et al., 1988) (Monteoliva-Sanchez and Ramos-Cormenzana, 1986, 1987; Monteoliva-Sanchez et al., 1988; Ohno et al., 1979). Increasing the salt concentration in the medium resulted in an increase of cyclopropanoic acids with a concomitant decrease in the monounsaturated fatty acids. [*Pseudomonas*] *beijerinckii* and *Halomonas halmophila* mainly contained ubiquinone Q-9 (Collins et al., 1981).

"*Agarbacterium alginicum*" hydrolyzes agar, a property which can be lost upon continued laboratory culture. The alginase of this bacterium has been studied in some detail (Williams and Eagon, 1962).

Calvo et al. 1988 were the first authors to report the existence of bacteriophages active against moderately halophilic bacteria. They demonstrated the existence of temperate phages in 52% of their *D. halophila* strains. Phage F9-11 (isolated from *D. halophila* strain F9-11) was studied in more detail and possessed an isometric head and a noncontractile tail. The phage could replicate at a wide range of marine salt concentrations, from 2.5% to 15%. Its stability seemed to be influenced by the osmolarity of the medium rather than by the NaCl concentration (Calvo et al., 1988).

The Genus *Frateuria*

JEAN SWINGS

The genus *Frateuria* comprises bacteria formerly classified as *Acetobacter aurantius* (Kondo and Ameyama, 1958). These are strains isolated from the plant *Lilium auratum*, which are brown, pigment-producing, polarly-flagellated, acetic acid-like bacteria. They were thought by Asai (1968) to be an evolutionary “intermediate” between *Pseudomonas* and *Gluconobacter*, and the position of these “intermediate” strains was discussed in a separate chapter. Within the acetic acid bacteria, their assignment either to *Gluconobacter* or *Acetobacter* has been difficult (Swings et al., 1980; Yamada et al., 1976). Since DNA-rRNA hybridization studies showed that these isolates are quite removed from the family *Acetobacteraceae*, the new genus *Frateuria* was created for them (Swings et al., 1980). *Frateuria* belongs in the Proteobacteria in subclass gamma sensu Stackebrandt et al. (1988) (see The proteobacteria: Ribosomal RNA Cistron Similarities and Bacterial Taxonomy in the second edition). In *Bergey's Manual of Systematic Bacteriology*, *Frateuria* was treated as a separate genus (Swings et al., 1984).

Habitats

Only two habitats of *Frateuria* are known, *Lilium auratum* (Kondo and Ameyama, 1958) and the fruit of the raspberry *Rubus parvifolius* (Yamada et al., 1976). Only 14 strains are known and described in the literature.

Isolation

Isolation from Raspberries (*Rubus parvifolius*) (Yamada et al., 1976)

The picked raspberries were incubated at 30°C in a medium containing glucose, 10 g; ethanol, 5 ml; yeast extract, 5 g; peptone, 3 g; and acetic acid 0.3 ml, per liter of 10% potato extract adjusted to pH 4.5. After the enrichment culture, typical acetic acid-like bacteria were selected on CaCO₃ plates, (see The Genera *Acetobacter* and *Gluconobacter* in the second edition), where they dissolved the calcium carbonate.

Identification

As *Frateuria* possesses the phenotypical features of the family Acetobacteraceae (see The Genera *Acetobacter* and *Gluconobacter* in the second edition), it was initially classified as an acetic acid bacterium. The minimal phenotypic description is as follows: Gram-negative, strictly aerobic, polarly flagellated rods when motile, requiring no growth factors, producing a water-soluble brown pigment on glucose-yeast extract-CaCO₃ agar, producing ubiquinone (menaquinone) with eight isoprenoid units (MK-8) and H₂S, able to grow at pH 3.6 and on Frateur's Hoyer mannitol medium; producing acid from ethanol, glucose, and xylose; lacking oxidase and gelatinase; not reducing nitrates; not hydrolyzing starch.

Frateuria presents another example of the unreliability of using solely phenotypic characterizations at the inter- and suprageneric levels in bacteriology. The production of acetic acid from ethanol and the growth at pH 3.6 suggest a relationship with the acetic acid bacteria which is not justified by more detailed phenotypic analysis. Additional methods are necessary in order to identify the genus *Frateuria* unambiguously, e.g., the types of ubiquinones formed, cellular fatty acid composition and DNA-rRNA hybridization analysis. *Frateuria* typically produces the ubiquinone MK-8, whereas *Gluconobacter* produces MK-10 and *Acetobacter* MK-9 or MK-10 (Yamada et al., 1976). *Frateuria* has an unusual fatty acid profile, consisting of the iso-branched-chain acid of C_{15:0}, which is different from those of *Acetobacter* or *Gluconobacter* (Yamada et al., 1981) and which is more closely related to *Xanthomonas maltophilia*. The application of DNA-rRNA hybridizations constituted the ultimate proof that *Frateuria* is not related to the acetic acid bacteria (subclass alpha of the Proteobacteria), but constituted a separate genus within subclass gamma. The acid-tolerant, nitrogen-fixing bacterium isolates from sugarcane resembled *Frateuria* by its production of a brown diffusible pigment and of H₂S, its lack of growth factor requirements, and its growth on 30% glucose (Cavalcante and Döbereiner, 1988), but it could be assigned unambiguously to the

genus *Acetobacter* by DNA-rRNA hybridizations (Gillis et al., 1989) (see The Genera *Acetobacter* and *Glucenobacter* in the second edition). The genus *Frateuria* currently comprises only one species, *Frateuria aurantia* (Swings et al., 1980, 1984).

Physiological Properties

Good growth occurs on glucose-yeast extract- CaCO_3 agar and in beer wort. In peptone broth, yeast extract broth, and Hoyer's mannitol medium, growth is faint. In Hoyer's medium, NH_4^+ is used as a nitrogen source in the presence of mannitol as a carbon source. All *Frateuria* strains grow well on casamino acids, in contrast with the acetic acid bacteria. Growth factors are not required.

The oxidation of lactate was demonstrated on oxydograms. In an oxydogram (Frateur, 1950), several strains are streaked on 2% agar plus 2% Ca lactate. Lactate oxidation is shown by the precipitation of CaCO_3 . The ketogenic activity on polyalcohols was weak or doubtful. From glucose, 2-keto-, and 2,5-diketogluconic acids were formed but not 5-ketogluconic acid. The production of acid from D-glucose and D-xylose was marked, and the pH always dropped below 4. Ethanol, glycerol, D-arabinose, D-ribose, D-fructose, D-galactose, and D-mannose were also acidified (Swings et al., 1980). Ethanol concentrations above 5% were not tolerated. The majority of the strains still grew in 25 to 30% glucose concentrations, and, in this respect, they also resemble the acetic acid bacteria.

The Chromatiaceae

JOHANNES F. IMHOFF

Introduction

The Chromatiaceae are γ -Proteobacteria (Woese et al., 1985) and representatives of the phototrophic purple bacteria. They are also referred to as “purple sulfur bacteria” (together with the Ectothiorhodospiraceae) and typically grow under anoxic conditions in the light using as photosynthetic electron donor, sulfide, which is oxidized to sulfate via intermediate accumulation of elemental sulfur inside the cells. A number of species also can grow under chemotrophic conditions in the dark, either autotrophically or heterotrophically using oxygen as terminal electron acceptor in respiratory processes. Phototrophic growth, photosynthetic pigment synthesis, and internal membrane formation are strictly regulated by oxygen and become derepressed at low oxygen tension.

Phylogeny

The family Chromatiaceae comprises physiologically similar species and genera of the γ -Proteobacteria that carry out anoxygenic photosynthesis (Fowler et al., 1984; Guyoneaud et al., 1998; Imhoff et al., 1998). The Chromatiaceae form a well-defined phylogenetic group of the γ -Proteobacteria to which at present none of the purely chemotrophic bacteria is closely related. They are closely related to the Ectothiorhodospiraceae, a second family of the purple sulfur bacteria (Imhoff, 1984b). Both are phylogenetically distant from the phototrophic purple nonsulfur bacteria, which are α - and β -Proteobacteria.

The 16S rDNA nucleotide sequences of most Chromatiaceae species are available and form the basis for a new taxonomy of this family (Cauette et al., 1997; Guyoneaud et al., 1998; Imhoff et al., 1998). Positive correlation between similarities of 16S rDNA sequences and particular phenotypic properties were taken as an indication of the importance of these properties in achieving a phylogenetically oriented taxonomy

that includes both genetic and phenotypic information for classification (Imhoff et al., 1998). It was suggested that the salt response is one important taxonomic criterion in such a taxonomic system of the Chromatiaceae, because both the genetic relationship and the salt responses distinguish major phylogenetic branches of the Chromatiaceae and single genera. Both the genetic relationship and the salt responses enable, e.g., the halophilic *Halochromatium salexigens* and *Halochromatium glycolicum*, and the marine *Marichromatium gracile* and *Marichromatium purpuratum* to be distinguished from each other and from freshwater species such as *Allochromatium vinosum* and relatives (Table 1 and Fig. 1). This implies a separate evolutionary development in the marine and in the freshwater environment and points to the general importance of salt responses and possibly other ecological parameters for species formation and evolution (Imhoff, 2001a).

The genetic relatedness determined on the basis of 16S rDNA nucleotide sequences (as shown in Fig. 1) revealed that major phylogenetic branches of the Chromatiaceae contain 1) truly marine and halophilic species, 2) species that are motile by polar flagella, do not contain gas vesicles, and are primarily freshwater species, and 3) species with ovoid to spherical cells, the majority of which are nonmotile freshwater species containing gas vesicles. A number of species have considerably deep branching points in the phylogenetic tree, which depicts their genetic difference from all other bacteria within this group. Among these is *Isochromatium buderii* belonging to the group of marine species and *Thiolamprovum pedioforme*, which is clearly but distantly associated to the group of *Thiocapsa* species. To these species also belongs *Thiorhodococcus minor*, which shows variable association even to different groups if different methods are applied for the tree calculations. In the presented distance tree, *Thiorhodococcus minor* is associated to *Thiobaca trueperi*.

The marine branch includes the genera *Marichromatium*, *Halochromatium*, *Rhabdochromatium*, *Thiococcus*, *Thioflaviccoccus*,

Fig. 1. Phylogenetic tree based on 16S rDNA nucleotide sequences of Chromatiaceae. The 16S rDNA sequences were aligned using the ClustalX program and corrected manually. Calculations were made using maximum likelihood and distance methods. The presented consensus tree was constructed using distance matrices as published previously (Imhoff et al., 1998). Bootstrap analyses with 100 resamplings were performed to obtain estimates for phylogenetic tree topologies. Values at the nodes correspond to bootstrap percentages. The bar corresponds to 5% estimated sequence divergence.

Thioalkalicoccus, *Thiorhodovibrio*, *Thiohalocapsa* and *Isochromatium* (Fig. 1). Three genetically related species of this group, which are adapted to the lower range of salt concentrations of brackish and marine habitats (*Thiococcus pfennigii*, *Thioalkalicoccus sibiricus* and *Thioflaviccoccus mobilis*), are clearly distinct from all others by containing bacteriochlorophyll β and by the presence of tubular internal membranes (Bryantseva et al., 2000; Imhoff and Pfennig, 2001b).

Another major branch of the Chromatiaceae is represented mainly by freshwater species (Imhoff et al., 1998). Most of these bacteria do not have a specific requirement for salt, and according to the definitions given by Imhoff (2001a), are considered as freshwater bacteria. They are routinely grown in freshwater media. Several of these bacteria frequently were observed also in marine coastal habitats. Because they are tolerant to salt concentrations of brackish and marine waters and physiologically among the most versatile purple sulfur bac-

teria, they may compete with the marine species of purple sulfur bacteria, in particular at low salt concentrations. Their salt tolerance is sufficient to enable development and competition in numerous coastal habitats. Some species of this group, such as *Thiocapsa litoralis* (Puchkova et al., 2000), even may grow better at minor salt concentrations (1% NaCl) than in its complete absence. This branch includes the genera *Chromatium*, *Allochromatium*, *Thermochromatium* and *Thioystitis* in one group, which are motile forms without gas vesicles. The majority of the genera of a second group (including *Thiocapsa*, *Thiolamproyovum*, *Thiobaca* and *Lamprocystis*) is characterized by nonmotile forms with gas vesicles. *Lamprocystis roseopersicina* is one of the rare cases where gas vesicles are formed and the cells are in addition motile by flagella. *Thiobaca trueperi* is a motile rod without gas vesicles (Rees et al., 2002). *Thiocapsa roseopersicina*, one of the best known species of this group, does not form gas vesicles. So far, unpublished sequences of *Thiodictyon* species indicate their association to

the group around *Thiocapsa* species. The 16S rDNA sequences from *Thiospirillum jenense*, *Lamprobacter modestohalophilus* and *Thiopedia rosea* are not yet available.

Taxonomy

Increasing accumulation of chemotaxonomic and phylogenetic data led to a redefinition of the Chromatiaceae, including the placement of only those purple sulfur bacteria into the family that deposit elemental sulfur inside the cells (Imhoff, 1984b). This definition of Chromatiaceae includes phototrophic purple sulfur bacteria capable of depositing globules of elemental sulfur microscopically visible inside the cells and agrees with Molisch's definition of the "Thiorhodaceae" (Molisch 1907). It is in line with their phylogenetic separation from other phototrophic purple sulfur bacteria, the Ectothiorhodospiraceae (Fowler et al., 1984; Imhoff and Sling, 1996; Imhoff et al., 1998). This definition is, however, in contrast to that of Bavendamm (1924) who included all phototrophic purple bacteria that use sulfide as sole photosynthetic electron donor, and during oxidation, form globules of elemental sulfur, either inside or outside the cells (Pfennig and Trper, 1971; Pfennig and Trper, 1974).

Differentiation of Chromatiaceae and Ectothiorhodospiraceae

Both, Chromatiaceae and Ectothiorhodospiraceae are families of the Chromatiales and also called "phototrophic purple sulfur bacteria." Traditionally, the most important and easily recognized distinguishing property within the Chromatiales is the deposition of elemental sulfur during growth on sulfide. Under anoxic conditions in the light, all Chromatiales are capable of photolithoautotrophic growth and using sulfide or elemental sulfur as electron donor. Elemental sulfur globules accumulate as an intermediate oxidation product of sulfide. Sulfur globules appear microscopically visible either inside the cells (Chromatiaceae) or outside the cells (Ectothiorhodospiraceae). The distinction has traditionally been made by microscopic observation and in most cases is without problems. In one of the recently described species of the Ectothiorhodospiraceae, *Thiorhodospira sibirica*, however, sulfur globules remain attached to the cells and, according to microscopic observations, are located in the cell periphery or the periplasmic space of the cells (Bryantseva et al., 1999). (The localization of sulfur globules in Chromatiaceae is discussed in the subsection Sulfur Metabolism).

Marked differences between representatives of the two families are seen in the 16S rDNA nucleotide sequences, as depicted in a number of characteristic signatures and in their overall sequence distance (Fig. 1).

The two families can also be clearly distinguished by a number of chemotaxonomic properties. Significant differences between Chromatiaceae and Ectothiorhodospiraceae occur in quinone, lipid and fatty acid composition (see Imhoff and Bias-Imhoff, 1995). Characteristic glucolipids are present in Chromatiaceae species, but absent from Ectothiorhodospiraceae (Imhoff et al., 1982). While C-16 fatty acids (in particular C-16:1) are the major components in Chromatiaceae, C-18 fatty acids (in particular C-18:1) are dominant in Ectothiorhodospiraceae, and C-16:1 is only a minor component in this latter group. In addition, the lipopolysaccharides are significantly different in members of the two families (Weckesser et al., 1979; Weckesser et al., 1995). The lipid A of all investigated Chromatiaceae (*Allochromatium vinosum*, *Thermochromatium tepidum*, *Thiocystis violacea*, *Thiocapsa roseopersicina* and *Thiococcus pfennigii*) is characterized by a phosphate-free backbone with D-glucosamine as the only amino sugar, which has terminally attached D-mannose and amide-bound 3-OH-C-14:0. In the lipid A of all tested Ectothiorhodospiraceae (*Ectothiorhodospira vacuolata*, *Ect. shaposhnikovii*, *Ect. haloalkaliphila* and *Hlr. halophila*), phosphate is present, 2,3-diamino-2,3-dideoxy-D-glucose is the major amino sugar (D-glucosamine is also present), D-mannose is lacking (D-galacturonic acid and D-glucuronic acid are present instead), and quite remarkably, 3-OH-C-10:0 is present as an amide-bound fatty acid (Zahr et al., 1992; Weckesser et al., 1995). These distinctive properties of the lipid A appear to be characteristic features of the two families.

Genera and Species of Chromatiaceae

In the traditional classification, morphological properties such as cell form and size, motility, presence of gas vesicles, and formation of cell aggregates were properties of major relevance. Because this classification was not in congruence with the phylogenetic relationships within the Chromatiaceae species, a reclassification was proposed on the basis of 16S rDNA sequence similarities and with support of selected phenotypic properties (Guyoneaud et al., 1998; Imhoff et al., 1998). New species and genera of Chromatiaceae described since the last edition of this handbook are *Thiorhodovibrio winogradskyi* (Overmann et al., 1992b), *Rhabdochromatium marinum* (Dilling et al., 1995), *Halochromatium glycolicum* (Caumette et al., 1997), *Thiorhodo-*

coccus minor (Guyoneaud et al., 1997), *Thioalkalicoccus limnaeus* (Bryantseva et al., 2000), *Thiocapsa litoralis* (Puchkova et al., 2000), *Thioflaviccoccus mobilis* (Imhoff and Pfennig, 2001b) and *Thiobaca trueperi* (Rees et al., 2002). The species of the Chromatiaceae and some selected characteristic properties are shown in Table 1.

Ecology of Chromatiaceae

Purple sulfur bacteria are widely distributed in nature and are found in all kinds of stagnant water bodies. Ecological niches are those anoxic parts of waters and sediments that receive light of sufficient quantity and quality to allow phototrophic development. The colored blooms often formed by purple sulfur bacteria, already can be seen with the naked eye and naturally have attracted many scientists. In addition to these macroscopically visible blooms, purple sulfur bacteria develop at a level not visible to the naked eye, as is indicated by positive enrichment cultures that were often obtained from sediments or water samples containing hydrogen sulfide but not showing visible accumulations of colored bacteria (e.g., Bavendamm, 1924; Pfennig, 1967; Imhoff, 1988b; Imhoff, 2001a).

Winogradsky (1888) gave a comprehensive description of the different morphological types of purple sulfur bacteria that he observed in samples from nature and raw cultures. Later investigators used Winogradsky's descriptions for identification of purple sulfur bacteria in visible enrichments and natural habitats. In his monograph on the colorless and purple sulfur bacteria, Bavendamm (1924) gave a first detailed account on their ecology, with his own observations and a review of the older literature. A number of more recent reviews consider ecological aspects and the distribution of purple sulfur bacteria in nature (Kondratieva, 1965; Pfennig, 1967; Pfennig, 1989a; Gorlenko et al., 1983; Van Gemerden and Beftink, 1983; Lindholm, 1987; Imhoff, 1988b; Imhoff, 1992; Imhoff, 2001a; Madigan, 1988; Van Gemerden and Mas, 1995).

The most important properties that determine the development and distribution of phototrophic bacteria in nature are the availability of light, the light intensity, and the concentrations of sulfide and oxygen, which form counter-current gradients in most of the natural habitats of purple sulfur bacteria where sulfide is produced by biological sulfate reduction. The depth at which phototrophic sulfur bacteria develop is largely restricted to the concomitant presence of light and sulfide. Some of the microbial activities that determine slope and position of these gradients, such as oxygen production by algae and

cyanobacteria and sulfide oxidation by phototrophic bacteria, show diurnal, light-dependent fluctuations. Others, such as sulfide production by sulfate-reducing bacteria and oxygen consumption by respiratory bacteria, do not. Because of these processes, the sulfide horizon rises at night and falls again during the day. The motile phototrophic purple bacteria are able to follow the moving sulfide horizon. Under favorable conditions separate layers of green sulfur bacteria are formed underneath layers of phototrophic purple bacteria and of algae and cyanobacteria. Frequently, however, mixed communities of purple and green sulfur bacteria are observed, and purple nonsulfur bacteria regularly accompany the mass development of phototrophic sulfur bacteria.

The Role of Hydrogen Sulfide

The ability of phototrophic sulfur bacteria to oxidize sulfide and other reduced sulfur compounds under anoxic conditions is one of their most characteristic and ecologically important properties. One of the possible final stages of anaerobic decomposition of organic matter is performed by sulfate-reducing bacteria. Whenever the activity of sulfate-reducing bacteria in a sediment is sufficient to raise the sulfide horizon into the photic zone, development of phototrophic sulfur bacteria is possible. Concentrations of sulfide and elemental sulfur and the relations of the different phototrophic bacteria to these compounds are significant factors in determining patterns of natural dominance and successful competition. Of particular importance are the bacterial affinities for these two sulfur compounds, their oxidation rates, the ability to utilize external elemental sulfur, and the ability to store elemental sulfur inside or outside the cells (Van Gemerden, 1974). The intracellular storage of elemental sulfur by Chromatiaceae gives these bacteria a clear advantage over those bacteria which store elemental sulfur outside the cells (green sulfur bacteria and purple nonsulfur bacteria). All elemental sulfur formed by Chromatiaceae is inaccessible to other bacteria, while the extracellularly formed elemental sulfur, e.g., by green sulfur bacteria is also available to Chromatiaceae. Therefore, intracellular stored elemental sulfur is of inestimable value for these bacteria: 1) under conditions of external sulfide depletion in the light, it serves as a reservoir of photosynthetic electron donors; 2) under dark conditions and in the presence of oxygen, it may support endogenous respiration (Breuker, 1964; Kämpf and Pfennig, 1986); and 3) under anoxic conditions in the dark, it may serve as an electron acceptor during endogenous fermentation of

stored carbohydrates (Hendley, 1955; Van Gernerden, 1968a; Van Gernerden, 1968b).

The Relations to Oxygen

Although Chromatiaceae are basically anaerobic bacteria and photosynthetic metabolism depends on light and oxygen-deficient conditions, some of the species are considerably tolerant to oxygen and flexible in their metabolism. Many purple sulfur bacteria are able to make use of the oxygen and perform respiratory energy transformations (Kondratieva et al., 1975; Kämpf and Pfennig, 1980).

At least two strategies enable growth, reproduction and successful competition of Chromatiaceae in the overall oxic environment, and are ecologically important: 1) true adaptation by metabolic flexibility in energy conservation, i.e., the ability to readily use both photosynthetic and respiratory mechanisms and 2) the development in and effective use of anoxic niches in an apparent oxic environment.

The first strategy enables the facultative respiring phototrophic bacteria to develop under diurnal oscillating conditions as part-time phototrophs and part-time chemotrophs at the oxic/anoxic chemocline in natural gradient systems. In particular, *Thiocapsa roseopersicina* is of high metabolic flexibility and this species is well equipped to take advantage of changing conditions from oxic/dark to anoxic/light conditions, and even simultaneously drives respiration and photosynthesis (De Wit and van Gernerden, 1990a; De Wit and van Gernerden, 1990b; Schaub and van Gernerden, 1994). Respiratory capabilities not only are of advantage in environments with steep chemical and physical gradients (where during diurnal cycles, changes of the light regime and of oxic to anoxic conditions occur), but also in situations of prolonged darkness where only respiration is possible. *Thiocapsa roseopersicina* also is a good candidate to grow under chemolithotrophic conditions during prolonged dark periods (see Imhoff, 2001a).

An interesting example of the second strategy is the strictly phototrophic *Marichromatium purpuratum*, which has adapted to anoxic niches in the bulk oxic environment and even succeeded in niches in the open ocean. Originally, it was isolated from a strictly oxygen-demanding marine sponge, which contained massive cell densities of this species (Imhoff and Trüper, 1976; Imhoff and Trüper, 1980). Later, a *Didemnum* species revealed similar mass accumulations of this species (see Imhoff, 1992), and more recently, *Marichromatium purpuratum* was isolated from the stomach of marine copepods that have a translucent chitin mantle and thrive in oxic ocean waters (Proctor, 1997).

The Role of Light

Not only the quantity, but also the quality of light is of major importance for the development of phototrophic bacteria, and owing to the different pigment composition of various phototrophic bacteria, light is also a selective environmental factor. The light quality required by a phototrophic bacterium is reflected in the absorption spectra of the photosynthetic pigment-protein complexes and is a characteristic property for a particular species or group of phototrophic bacteria. Most of the phototrophic purple bacteria have bacteriochlorophyll α , with long-wavelength absorption maxima between 800 and 900 nm. Only a few species have bacteriochlorophyll β , with absorption maxima at 980–1035 nm.

Light absorption in water masses and sediments follows completely different scenarios (see Imhoff, 1992 and Pfennig, 1989a). In water, the potential light penetration is many meters, while in sediments because of the strong light absorption (Taylor, 1964), the development of phototrophic bacteria is restricted to the uppermost few millimeters. Therefore, the availability of light severely limits the development of phototrophic bacteria in sediments and often they form thin, colored layers below a surface layer of cyanobacteria (Pfennig, 1989a; Imhoff, 1992). Bacteriochlorophyll absorption is of major importance in sediments, particularly sandy sediments where infrared radiation deeply penetrates (Hoffmann, 1949) and favors the growth of bacteria that use photosynthetic pigments (such as bacteriochlorophyll β) with absorption maxima in the far infrared. Indeed, bacteria with this pigment (e.g., *Thiococcus pfennigii*) are particularly well adapted to sediments not permanently covered by water or covered only by a thin layer such as occurs in many coastal habitats. These bacteria are common to shallow coastal habitats and most of them have been isolated from such locations, but they are rarely encountered in deeper water bodies.

In deeper layers of water, the use of bacteriochlorophylls for light harvesting is limited by the significant absorption of infrared radiation (particularly above 800 nm) by water. Therefore, the role of carotenoids (absorption maxima at 450–550 nm) in light harvesting increases with the water depth. The purple bacteria, in particular those with okenone as carotenoid, have an advantage in deeper water layers because of the efficient light absorption of this pigment.

Habitats of Chromatiaceae

In addition to the important and selective environmental factors described above (anoxic con-

ditions, and presence of hydrogen sulfide and light), physical and chemical properties such as temperature and salt concentration are important environmental factors relevant for the natural distribution of these bacteria. Most frequently, habitats are those of moderate temperatures, but Chromatiaceae also have been found in thermal springs (Madigan, 1986), and even evidence for their presence in sea ice has been obtained (Petri and Imhoff, 2001). Various species of the Chromatiaceae specifically inhabit different types of freshwater, marine and hypersaline habitats. Because of the striking difference between freshwater and saline habitats, both types of habitats of Chromatiaceae will be discussed separately.

It should be noted that in many investigations tentative identification of purple sulfur bacteria in natural samples was achieved on the basis of microscopic morphological characteristics. Because these properties do not allow species to be identified, assignment of bacteria from natural samples to species and genera is quite problematic, unless isolates are obtained and characterized. In the following, the designations given by the authors of the cited references are used; if the species mentioned has been renamed, the new name is given.

Freshwater Habitats

Visible accumulations of phototrophic sulfur bacteria occur temporarily in the anaerobic parts of all kinds of freshwater habitats (lakes, shallow ditches, ponds, small stagnant water bodies in forests and botanical gardens, and mountain lakes). In such habitats, development usually proceeds during summer or fall, when abundant hydrogen sulfide is formed by sulfate-reducing bacteria from decaying plant material or from organic pollution. Pink to purple-red blooms of Chromatiaceae are often detected within the water itself or in the form of more-or-less profuse patches that cover the upper or lower side of dead leaves or the mud surface. Early observations on such habitats were already made in the late 19th century (Ehrenberg, 1838; Lankester, 1873; Cohn, 1875; Kützing, 1883; Winogradsky, 1888; Miyoshi, 1897), but such observations were much more numerous in the 20th century (see below).

The largest and most significant freshwater environments of the phototrophic purple sulfur bacteria are lakes. These habitats are more constant over longer periods of time than others and therefore support more stable phototrophic communities. The blooms of purple (and green) sulfur bacteria usually occur several meters deep at the chemocline and are not visible at the water surface. Depending on the hydrographic conditions, major types of lakes can be differentiated

(Biebl and Pfennig, 1979; Pfennig and Trüper, 1992).

MEROMICTIC LAKES Permanently stratified meromictic lakes have an anaerobic, sulfide-containing hypolimnion which often consists of saline water. In these lakes, phototrophic bacteria can thrive at a more or less fixed depth over longer periods. Major fluctuations in the population density occur in response to seasonal differences in the intensity of sunlight and temperature and the associated consequences, including concentrations of sulfide. Examples of meromictic lakes with well developed blooms of purple red layers are the Ritomsee (Switzerland; Duggeli, 1924), the well-studied Lake Belovod (Russia; Kusnetzov, 1970; Sorokin, 1970) and Lake Cadagno (Switzerland; Bosshard et al., 2000) with blooms containing *Chromatium okenii*. Mixed populations of purple sulfur bacteria and green sulfur bacteria were found, e.g., in Suigetsu Lake and Kisaratsu Reservoir (Japan; Takahashi and Ichimura, 1968).

HOLOMICTIC LAKES In holomictic lakes that undergo mixing in spring and fall, the anaerobic and sulfide-containing hypolimnion reaches the highest level and hence the strongest illumination condition during summer stratification. Blooms of phototrophic bacteria develop in the uppermost part of the hypolimnion and form colored water layers or plates. In some lakes, this layer is dominated by green sulfur bacteria, in others, green and purple bacteria occur either in mixed populations (e.g., of *Ancalochloris*, *Pelochromatium* and *Lamprocystis*) as in the Pluss-See (northern Germany; Anagnostides and Overbeck, 1966) or develop in different, separated layers, as in Wintergreen Lake (United States; Caldwell and Tiedje, 1975). In this lake, green sulfur bacteria containing gas vesicles thrive below layers with *Thiopedia* and *Thiocystis* species. The Lunzer Obersee (Austria; Ruttner, 1962), the Rotsee (Switzerland; Schegg, 1971) and Lake Vechten (Netherlands; Steenbergen and Korthals, 1982) are examples of holomictic lakes in which populations of *Chromatium okenii*, *Thiopedia rosea* and *Lamprocystis roseopersicina* were reported as the dominant species occurring in purple-red layers. In the Banyoles karstic area of northeastern Spain, a number of small lakes with mass developments of purple sulfur bacteria exist (Guerrero et al., 1987) of which Lake Cisó with blooms of *Chromatium minus* has been studied in most detail (Van Gemerden et al., 1985; Gasol et al., 1991; Pedros-Alio and Guerrero, 1991).

SHALLOW WATER LAKES In more shallow lakes with a maximum depth of 15 m, in which the

anaerobic, sulfide-containing zone is primarily confined to the mud sediment and does not extend significantly into the water layers, mass developments of purple sulfur bacteria are more or less restricted to the sediments. Examples of this type of lake are the Kolksee and Edebergsee (northern Germany) with blooms of *Thiopedia* and *Pelochromatium* (Utermöhl, 1925), the Lunzer Mittersee (Austria) with blooms of *Chromatium okenii* and *Lamprocystis* (Ruttner, 1962), Mulizne Lake (Poland) with a *Thiopedia* bloom (Czeczuga, 1968), the monomictic Zaca Lake (California) with a *Thiopedia* bloom (Folt et al., 1989) and Haruna Lake (Japan) with a *Chromatium* bloom (Takahashi and Ichimura, 1968).

SULFUR SPRINGS Sulfur springs create aquatic habitats with relatively constant sulfide supply (Winogradsky, 1888), and if exposed to the light, may be suitable habitats for phototrophic sulfur bacteria. Visible mass accumulations of green and purple sulfur bacteria were observed in the effluents of sulfur springs in Poland which contained 40–100 mg of H_2S /liter (Szafer, 1910; Strzeszewski, 1913). Green sulfur bacteria occurred as the predominant forms at higher sulfide concentrations, followed downstream by different species of purple sulfur bacteria. Purple sulfur bacteria also were found in warm sulfur springs (35–44°C) in Japan (Miyoshi, 1897). While growth temperatures up to 43°C are not uncommon for *Allochromatium vinosum* strains, the optimum growth temperature of 48–50°C with *Thermochromatium tepidum* is exceptional. This moderately thermophilic purple sulfur bacterium was isolated from the Stygian Springs of Yellowstone Park (Madigan, 1986).

WASTE WATER PONDS Anaerobic stabilization ponds of wastewater treatment plants also are habitats of purple sulfur bacteria. In general, conditions for the development of purple sulfur bacteria in waste-treatment lagoons are created when wastewater with a high organic load is treated in shallow ponds (1–2 m in depth) which favor the development of anoxic conditions and the formation of sulfide by sulfate-reducing bacteria (Holm and Vennes, 1970; Gloyna, 1971; Sletten and Singer, 1971). In such ponds, blooms of purple sulfur bacteria are mostly visible in spring and fall, while during summer, the ponds often turn green by unicellular algae. The most common purple sulfur bacteria in waste-treatment systems are *Thiocapsa roseopersicina*, *Thiocapsa rosea*, *Thiocapsa pendens* and *Thiolamprovum pedioforme* (Eichler and Pfennig, 1986). In addition, *Thiocystis violacea* and *Allochromatium* species are often present in small numbers.

Marine Habitats

The shorelines of the oceans with their numerous ecological niches can be considered as the most important places for the development of Chromatiaceae in the marine environment, and the most abundant and conspicuous developments of phototrophic bacteria can be found here. Conditions that favor the development of purple sulfur bacteria are found wherever quiet water is present, e.g., in small splash water ponds along rocky shores, in seawater pools and small puddles of salt marshes, in closed bays and large lagoons, in sediments of sandy beaches, salt marshes and tidal flats, and in muddy masses of decaying algae or seaweeds. In these places, bacterial sulfate reduction is facilitated by the degradation of decaying organic materials and the presence of abundant sulfate (Trüper, 1980). Such habitats have also been named “beach sulfureta” (Suckow, 1966) because they house a complete sulfur cycle including bacterial sulfate reduction and sulfide oxidation by phototrophic bacteria and by chemotrophic sulfur bacteria. Chromatiaceae are the most obvious and numerous phototrophic bacteria in these habitats. Since Warming (1875) described mass developments of purple sulfur bacteria on the coasts of Denmark, these bacteria have been found and studied along the ocean coasts all over the world (for reviews, see Pfennig, 1967; Pfennig, 1989a; Trüper, 1980; Pfennig and Trüper, 1981; Imhoff, 1988b; Imhoff, 1992; Imhoff, 2001a; Van Gemerden and Mas, 1995).

It is supposed that the metabolic versatility is an important property to explain their widespread occurrence in the highly dynamic and unstable marine coastal habitats (Imhoff, 2001a). Great metabolic versatility is of selective advantage at these habitats, and the most versatile phototrophic purple bacteria frequently are among the dominant species here (Molisch, 1907; Bavendamm, 1924; Trüper, 1970; Imhoff, 1992; Imhoff, 2001a). This versatility is reflected 1) in the ability to use different possibilities of energy conservation and different photosynthetic electron donors, in particular sulfide and thiosulfate, 2) in the high potential of photoheterotrophic growth together with the ability to assimilate sulfate as sole sulfur source, and 3) in the ability to grow chemotrophically under oxic conditions in the dark, either autotrophically or heterotrophically. In particular *Allochromatium vinosum*, *Marichromatium gracile*, *Thiocystis violacea* and *Thiocapsa roseopersicina* have regularly been observed and isolated from marine coastal habitats. Other species frequently encountered are *Allochromatium warmingii*, *Thiocystis violascens*, *Allochromatium minutissimum*, *Thiocystis minor*, *Thiocapsa rosea*, *Marichromatium purpu-*

ratum and *Isochromatium buder* (Trüper, 1970; Trüper, 1980; Imhoff, 1988b; Imhoff, 1992; Imhoff, 2001a; Pfennig, 1989a).

SEDIMENTS AT MARINE SHORELINES Owing to their dependence on the process of bacterial sulfate reduction, which is by and large restricted to the sediments, phototrophic sulfur bacteria are more or less confined to the sediments or to sediment-associated waters that receive sulfide from these sediments. Whenever the production of sulfide is not sufficient to penetrate into the water, development of these bacteria is restricted to the sediment. Under such conditions, they often form thin colored layers within the top millimeters of the sediments. Sandy beaches with such colored layers were called the "Farbstreifensandwatt" (Schulz, 1937; Schulz and Meyer, 1939; Hoffmann, 1942; Hauser and Michaelis, 1975). Microbial mats of phototrophic microorganisms, including layers of purple sulfur bacteria, also are common to sheltered areas of the Waddensea and of salt marshes.

An outstanding example is found in the microbial mats of the Great Sippewissett Salt Marsh (Cape Cod, MA, United States), where laminated microbial mats of unusual thickness regularly occur during summer and one very well developed mat was described by Nicholson et al. (1987). In these sandy intertidal sediments, the mats were about 10 mm thick and comprised four to five distinctly colored layers. Phototrophic purple sulfur bacteria of the central pink layer and the directly underlying peach-colored layer were identified. The dominant bacteria of the pink layer were considered to be *Thiocapsa roseopersicina* and those of the peach layer were recognized as *Thiococcus pfennigii* on the basis of the presence of bacteriochlorophyll β and the bundles of tubular intracellular membranes in the coccoid cells. A second bacterium with bacteriochlorophyll β was isolated from this layer. It resembles *Thiococcus pfennigii* in many properties but is a motile coccus and was described as a new species, *Thioflavococcus mobilis* (Imhoff and Pfennig, 2001b). Also two new species of purple nonsulfur bacteria have been described recently from this location. In the peach-colored layer of the mats, small spirilloid bacteria were detected by scanning electron microscopy (about 1% of total cells), which were isolated and found to contain bacteriochlorophyll β and to exhibit a number of unusual characteristics. This bacterium was described as the new species *Rhodospira trueperi* (Pfennig et al., 1997). Another purple nonsulfur bacterium, *Roseospirillum parvum*, also was isolated from this habitat (Glaeser and Overmann, 1999). In addition, a greater number of isolates of purple and green sulfur bacteria

are known to originate from this salt marsh (Trüper, 1970).

COASTAL WATERS, LAGOONS, AND FJORDS There are a number of reports on the development of massive blooms of phototrophic bacteria, sometimes called "red waters" in shallow coastal waters such as lagoons but also in saline lakes and anoxic fjords. Examples are Lake Faro in Sicily (Genovese, 1963; Trüper and Genovese, 1968); the Mar Piccolo near Trento (Cerruti, 1938); Veliko and Male Jezero on the Dalmatian island of Mljet (Cviic, 1955; Cviic, 1960); the Bay of Tunis (Heldt, 1952; Stirn, 1971) and Bietri Bay of the Ebrie Lagoon, Ivory Coast (Caumette, 1984); the Etang du Prevost near Montpellier, France (Caumette, 1986); lagoons at Messolonghi and Aitolikon in Greece (Hatzikakidis, 1952; Hatzikakidis, 1953); the Solar Lake on the Sinai Peninsula (Cohen et al., 1977); Lake Mogilnoye on the Arctic island of Kildin (B. L. Isachenko [1914], "Studies of bacteria of the Arctic Ocean," cited in Gorlenko et al., 1978; Gorlenko et al., 1978) and others.

THE BLACK SEA In contrast to estuarine or near-shore marine habitats, the oxygenated waters of the open ocean have been found to be devoid of phototrophic sulfur bacteria. A special case of a stratified marine habitat is the Black Sea, a large, meromictic enclosed basin that is not part of the open ocean. Although its anoxic layer did not reach the photic zone and the development of anoxygenic phototrophic bacteria seemed to be impossible, their presence in the Black Sea was first demonstrated by Kriss and Rukina (1953). Later, several Chromatiaceae species (*Thiocapsa roseopersicina* and *Allochromatium warmingii*), but also green sulfur bacteria (*Chlorobium phaeobacteroides*) were obtained in enrichment and pure cultures from anoxic dark Black Sea bottom sediments at 600 and 2240 m depth (Hashwa and Trüper, 1978). These authors assumed survival of the phototrophic bacteria that may be washed away from their estuarine environment into the dark layers of the Black Sea, but excluded active growth under the anoxic dark conditions in the deep sediments. The situation was much different approximately 10 years later, when the chemocline reached horizons (68 to 90 m) receiving light of minor intensities. At that time large amounts of bacteriochlorophyll, indicative of brown-colored green sulfur bacteria, were detected (Repeta et al., 1989; Jørgensen et al., 1991; Overmann et al., 1992a). Apparently light intensities at the depth of the chemocline still were insufficient to support the development of purple sulfur bacteria.

SEA ICE Sea ice is generally regarded to be oxic but not anticipated to have anoxic niches and

therefore not to be a habitat of anoxygenic phototrophic bacteria. The possible existence of anoxic niches within the complex system of small brine channels within sea ice was concluded from the presence of various types of anaerobic and potentially anaerobic bacteria in the interior of sea ice from the Baltic Sea (Petri and Imhoff, 2001). As revealed by 16S rDNA analyses, a Chromatiaceae species is a major component within a distinct layer of this sea ice. These findings point out that sea ice may contain potential niches for anoxygenic phototrophic bacteria. Again, oxygen tolerance and respiratory capabilities are considered to be excellent prerequisites for them to live in such a habitat (Petri and Imhoff, 2001).

SALT AND SODA LAKES Though many habitats of phototrophic bacteria in the coastal zone contain brackish waters, others are more concentrated than seawater. Shallow waters in splash water ponds, coastal lagoons, closed basins and the like, which receive intensive illumination from the sun are subject to evaporation. As a consequence, inorganic salts and organic matter accumulate and chances for the occurrence of anoxic conditions and the development of anoxygenic phototrophic bacteria increase. These waters have higher fluctuations in salt concentrations and quite often the salinities are higher than in seawater. Many isolates from such places are tolerant to a wide range of salt concentrations and some require or tolerate salt concentrations above seawater salinity (Imhoff, 1988b; Imhoff, 1992; Imhoff, 2001a). Particularly high fluctuation occurs in the so-called "splash water ponds" along rocky coasts and these have been found to contain phototrophic sulfur bacteria. Such habitats were studied in Japan (Taga, 1967), Helgoland (Germany), and Yugoslavia (Imhoff, 1988b).

Thalassohaline waters occur as natural evaporation pools of marine waters or as man-made evaporation ponds of marine salterns. A different type of hypersaline environment is found in various athalassohaline waters of inland salt water lakes. A few prominent examples of such lakes are the Great Salt Lake (Utah), the Dead Sea (Israel), and the soda lakes of the Wadi Natrun in Egypt. These habitats have largely different ionic compositions (Imhoff et al., 1979). Evidence for the presence of ecological niches for halophilic phototrophic purple bacteria and their occurrence is available for most of these lakes, and in some of them, the development in visible masses has been described (see Imhoff, 1988b; Imhoff, 1992; Imhoff, 2001a). Numerous isolates have been obtained and a number of new species of phototrophic purple sulfur bacteria have been described from marine salterns (Caumette, 1993; Caumette et al., 1988; Caumette, 1991; Caumette, 1994), alkaline soda lakes in the Egyptian Wadi Natrun (Jannasch, 1957; Imhoff and Trüper, 1977; Imhoff and Trüper, 1981; Imhoff et al., 1979), Russian soda lakes in Siberia and Mongolia (Bryantseva et al., 1999; Bryantseva et al., 2000), and the Solar Lake (Cohen et al., 1977; Imhoff, 1983; Caumette et al., 1997).

Selective Enrichment of Chromatiaceae

Ever since the first experimental studies on purple sulfur bacteria by Winogradsky (1888), it has been customary to grow these bacteria in the laboratory in raw enrichment cultures. These well-known Winogradsky columns are set up in tall glass cylinders, e.g., with plant residues, CaSO_4 , anaerobic mud and water of a natural habitat. Traditionally, they are incubated in dim light. Variations of this column technique are discussed by Pfennig (1965) and van Niel (1971). The preparation and development, as well as the advantages and limitations, of the different types of such long-lasting raw cultures are well described (Winogradsky, 1888; Buder, 1915; Schrammeck, 1934; Schlegel and Pfennig, 1961; Pfennig, 1965; van Niel, 1971). Most purple sulfur bacteria that thrive in Winogradsky columns also can be grown and isolated by direct methods in synthetic media (see the section Isolation in this Chapter).

Alternatively, phototrophic sulfur bacteria may be selectively enriched from most natural habitats in suitable media under anoxic conditions and in the light. Medium 1 (see below), eventually with modifications and different supplements, is a good choice for the selective enrichment of Chromatiaceae from freshwater and marine habitats. For this purpose, pH adjustment to 7.2 and 7.4 is recommended. For the successful enrichment of purple sulfur bacteria, it is important to realize that many species quite specifically occur in characteristic ecological niches. The species composition of the inoculum is, therefore, of primary importance for the outcome of enrichment experiments.

Of general importance for the selectivity of enrichment cultures for Chromatiaceae (and other anoxygenic phototrophic bacteria) are the culture media and the incubation conditions, in particular, the mineral salts composition and salinity, the concentration of nutrients, the presence of vitamins, as well as pH, temperature, light intensity and light regime. The choice of the carbon source is not critical for the success of such enrichment cultures because fermentative processes in natural enrichments usually result in

the formation of acetate and/or other acids (propionate, butyrate and lactate), which are good substrates for the majority of the purple sulfur bacteria.

Sulfide Concentration

A number of species are inhibited by higher sulfide concentrations. Therefore, the sulfide concentrations should be kept as low as 1–2 mM, so that the cultivation of sensitive forms is not excluded. High population densities can be achieved only by repeated sulfide “feeding” (i.e., addition of a neutralized sulfide solution). *Thiopedia rosea* is exceptional in being inhibited by sulfide concentrations already above 0.6 mM, and the addition of sodium dithionite (50 mg for 1 liter) is required for cultivation of this bacterium (Pfennig and Trüper, 1992).

Salinity and Mineral Salts Composition

This is of special importance, if samples from marine and hypersaline environments are investigated. The salinity of the enrichment culture is usually adjusted according to the salinity of the inoculum. For marine isolates, it is sufficient to raise the NaCl concentration to 2–3%. Some isolates also require increased concentrations of magnesium (e.g., 0.3% $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$) and sometimes also of calcium (Biebl and Pfennig, 1978). Notably, the salinity of a natural habitat may not always be optimal for a particular isolate from the habitat. Therefore, use of enrichment media of different salinities may be useful for the isolation of a variety of species from the same sample.

Incubation Temperature

Temperature is important for the enrichment culture of Chromatiaceae. As a rule, at high incubation temperatures (28–35°C), a wide variety of different species are outgrown by single, fast-growing species. At low temperatures (15–22°C), the enrichment cultures develop more slowly and a larger number of different species may be present simultaneously. Elevated temperatures above 40°C are highly selective for moderately thermophilic species such as *Thermochromatium tepidum* (Madigan, 1986).

Illumination and Light Intensity

The various species of the purple sulfur bacteria differ with respect to the selective advantage they exhibit under different kinds of illumination. These differences can be exploited for the selective enrichment of certain groups of species (Pfennig, 1965; Pfennig, 1967). Two different illumination schemes with incandescent light are recommended here.

If continuous illumination at high light intensities of 1,000–2,000 lux, and an incubation temperature of about 30°C is used, the small and fast-growing Chromatiaceae can be expected to enrich, e.g., *Thiocapsa roseopersicina*, *Allochromatium vinosum*, *Allochromatium minutissimum*, *Thiocystis minor*, *Thiocystis violascens*, *Thiocystis violacea* and *Marichromatium gracile*.

Results may be different with intermittent illumination at low light intensities of 50–300 lux and an incubation temperature of about 20°C. Duration of the light and dark phases may be varied from 12 h light and 12 h dark (6 h light and 6 h dark) as proposed by Pfennig (1967) to 4 h light and 8 h dark (van Gernerden, 1974). Depending on the inoculum, the flagellated, large cell Chromatiaceae and those containing gas vesicles can be expected to enrich, e.g., *Thiospirillum jenense*, *Chromatium okenii*, *Chromatium weissei*, *Allochromatium warmingii*, *Isochromatium buderi*, *Thiocystis gelatinosa*, *Lamprocystis roseopersicina*, *Thiodictyon elegans*, *Thiocapsa rosea* and *Thiopedia rosea*. The flagellated forms keep swarming in the whole bottle (Pfennig, 1962) and can be further enriched by carefully pipetting the inoculum for subsequent enrichment cultures from the upper part of the culture bottle. During incubation of the enrichment cultures, at first, the nonmotile forms enrich at the bottom. Later, the cells containing gas vesicles tend to accumulate at the surface under the screw cap. This process can be accelerated by keeping the enrichment for a few days in a refrigerator at 4°C. For further enrichment, the floating cell mass is carefully pipetted from the surface and transferred to fresh medium.

The use of specific light filters can be of value for the enrichment of purple sulfur bacteria. Development of green sulfur bacteria with their long wavelength absorption maxima between 705 and 750 nm can be prevented when the enrichments are illuminated behind an infrared filter that transmits light only above 800 nm. The selective enrichment of bacteria that contain bacteriochlorophyll β , such as *Thiococcus pfennigii* (Eimhjellen et al., 1967; Eimhjellen, 1970) and *Thioflavicoccus mobilis* (Imhoff and Pfennig, 2001b) is achieved with an infrared filter that transmits radiation only above 900–1,000 nm.

Isolation

The first rational enrichment and isolation procedures for purple and green sulfur bacteria were developed by van Niel (1931). Further attempts to grow in pure culture the large-celled purple sulfur bacteria *Chromatium okenii* and *Thiospirillum jenense* led to the elaboration of a

synthetic medium that contains vitamin B₁₂ (Pfennig, 1965; Pfennig and Lippert, 1966). An advanced recipe of this medium will be given below (Medium 1). With slight modification, this culture medium allows the isolation and cultivation of most purple (and green) sulfur bacteria that occur in freshwater, estuarine and marine habitats.

Direct Isolation

As an alternative to enrichments followed by pure culture isolation, pure cultures may be obtained by directly inoculating agar media from natural samples without prior enrichment. This strategy has to be used whenever the analysis of the natural diversity is attempted and information on the natural abundance and distribution of the species in a sample is desired. Media with low selectivity are required for this approach. When the incubation time is adapted to the growth rates of slowly growing strains or of those not well adapted to the given conditions, separation in or on agar allows these cells to grow into small colonies that can be picked up for further transfers.

Deep agar dilution series (see below) should be prepared directly from the sample without prior enrichment in liquid culture. Even in this case, however, the incubation conditions for the agar cultures should closely resemble the conditions used for liquid enrichment cultures of the desired bacteria, i.e., use of low temperatures and low light intensities as indicated above is recommended.

Methods of direct isolation of the phototrophic bacteria from a natural sample use agar dilution series or inoculation of agar plates to separate the cells prior to incubation. For inoculation, a sample of water, mud, sludge, or even soil may be used as a homogeneous suspension in medium or in filter-sterilized water from the habitat. Samples containing less than 10 cells/ml need to be concentrated by centrifugation (agar dilution series) or filtration (agar plates). All methods for direct isolation are suitable for the determination of living cell counts, when known amounts of the sample are used in appropriate dilutions.

Isolation Procedures

MEDIA FOR CULTIVATION OF PURPLE SULFUR BACTERIA The composition and preparation of two different culture media are described below for the cultivation of purple sulfur bacteria. The first (Medium 1) is suitable for almost all purple bacteria presently in laboratory culture, including those species that are most difficult to grow

(e.g., *Thiopedia rosea*, *Thiospirillum jenense*, *Chromatium okenii* and *Thiodictyon elegans*). With minor modifications, this culture medium formulation was published by Pfennig (1965), Pfennig and Lippert (1966), Trüper (1970), Eichler and Pfennig (1988) and Pfennig and Trüper (1992). In addition, a second, very similar culture medium is given (Medium 2), which is easier to prepare and which allows the cultivation of most of the common purple sulfur bacteria (Biebl and Pfennig, 1978).

Medium 1 (Eichler and Pfennig, 1988)

The medium is prepared in a 5-liter bottle with four openings at the top. Two openings are connected to tubing: 1) a short, gas inlet tube with a sterile cotton filter and 2) an outlet tube for the medium, which reaches the bottom of the central part of the vessel at one end and has, at the other end, a silicon rubber tube with a pinchcock and a bell for aseptic dispensing of the medium into bottles. The other two openings have gas-tight screw caps. One of these openings is for the addition of sterile solutions and the other can serve as a gas outlet.

Solution 1

Distilled water	4,900 ml
KH ₂ PO ₄	1.7 g
NH ₄ Cl	1.7 g
KCl	1.7 g
MgSO ₄ · 7H ₂ O	2.5 g
CaCl ₂ · 2H ₂ O	1.25 g

Solution 1 is autoclaved for 45 min at 121°C in the 5-liter bottle, together with a teflon-coated magnetic stir bar. It is cooled to room temperature under an N₂ atmosphere with a positive pressure of 0.05–0.1 atm (a manometer for low pressures is required). The cold medium is saturated with CO₂ by magnetic stirring for 30 min under a CO₂ atmosphere of 0.05–0.1 atm. The sterile solutions 2 through 5 (see below) are then added through one of the screw-cap openings against a stream of either N₂ gas or, better, a mixture of 95% N₂ and 5% CO₂ while the medium is magnetically stirred.

For enrichment cultures or pure cultures from marine or estuarine habitats, 100 g of NaCl are added to solution 1 and the content of MgSO₄ · 7H₂O is increased to 15 g.

Solution 2: Vitamin B₁₂ Solution

A sterile-filtered stock solution containing 2 mg of vitamin B₁₂ in 100 ml of distilled water is prepared, and 5 ml are added to Solution 1.

Solution 3: Trace Element Solution SL 12

Distilled water	1 liter
Ethylene diamine tetraacetate-Na ₂	3.0 g
FeSO ₄ · 7H ₂ O	1.1 g
H ₃ BO ₃	300 mg
CoCl ₂ · 6H ₂ O	190 mg
MnCl ₂ · 4H ₂ O	50 mg
ZnCl ₂	42 mg
NiCl ₂ · 6H ₂ O	24 mg
Na ₂ MoO ₄ · 2H ₂ O	18 mg
CuCl ₂ · 2H ₂ O	2 mg

The salts are dissolved in the order given, the pH is adjusted to 2–3 with HCl, the solution is sterilized, and 5 ml are added to solution 1.

Solution 4: Na-bicarbonate Solution

A solution of 7.5% Na-bicarbonate is prepared, saturated with CO₂, autoclaved under a CO₂ atmosphere in a tightly closed bottle, and 100 ml are added to solution 1.

Solution 5: Sodium Sulfide Solution

A 10% Na₂S · 9H₂O solution is prepared in a screw-cap bottle, and after replacement of the air by N₂, the bottle is tightly closed and autoclaved. Twenty ml of the sterile solution are added to solution 1.

After combining and carefully mixing solutions 1 through 5, the pH of the medium is adjusted by stirring under an atmosphere of CO₂ (0.5 bar pressure) for approx. 40 min to pH 7.2. The medium is then immediately dispensed aseptically under pressure of N₂ (0.05–0.1 atm) into sterile 100-ml bottles with metal screw caps containing autoclavable rubber seals. A really small, pea-sized air bubble is left in each bottle to meet possible pressure changes. The tightly sealed screw-cap bottles can be stored for several weeks to a month in the dark. During the first 24 h, some trace metal (mainly iron) sulfides of the medium precipitate in the form of fine black particles. No other sediment should arise in the otherwise clear medium.

Supplement Solutions**Sulfide Solution for Feeding of Batch Cultures**

The amount of Na₂S · 9H₂O initially added to Medium 1 (higher initial amounts may be inhibitory for some species) will only produce very limited growth. After the sulfide and sulfur are completely oxidized, the bacteria stop growing and may be damaged by further illumination. To keep the cultures growing and to obtain high cell yields, it is necessary to feed the cultures several times with sterile, partially neutralized sulfide solution. Two different sulfide feeding solutions are prepared as follows:

Dissolve 3.6 g of Na₂S · 9H₂O in 100 ml of distilled water (a 0.15M solution) in a 250-ml screw-cap bottle. After replacement of the air by N₂, the bottle is tightly closed and autoclaved. To prepare the neutralized feeding solution, a measured amount of this solution is added to a sterile Erlenmeyer flask containing a magnetic stir bar. The solution is brought to about pH 7.3 by dropwise addition of sterile 1M H₂SO₄ on a magnetic stirrer. If too much acid is added, the sulfide solution becomes turbid owing to precipitation of elemental sulfur. The nearly neutralized solution is immediately used for feeding 100-ml bottle cultures. Depending on the population density, 1–2 ml are used for Chromatiaceae. Before the addition, an equivalent amount of culture medium is aseptically removed from the bottle culture.

Alternatively the method of Siefert and Pfennig (1984) offers a ready to be used, neutralized sulfide feeding solution. This solution is prepared in a 500-ml bottle with a small outlet at the bottom, connected by a rubber tube with a pinchcock to a test tube tightly closed by a screw cap (Siefert and Pfennig, 1984). In a volume of 250 ml of distilled water 7.0 g of Na₂S · 9H₂O and 2.65 g of Na₂CO₃ are dissolved and autoclaved under a CO₂ atmosphere. The sterile solution is saturated with CO₂ under pressure

(0.8 bar) until the pH is approx. 7.3. The solution is stored under CO₂ pressure and ready for use. For feeding of cultures, a small volume is pressure-released from the bottle into the test tube and transferred from this tube into the cultures by using a sterile pipette.

Thiosulfate Solution for Cultivation of Chromatiaceae

Cultures of purple sulfur bacteria that can use thiosulfate as an electron donor can be supplemented with 0.1% of this compound from a stock solution (dissolve 10 g of Na₂S₂O₃ · 5H₂O to a final volume of 100 ml of distilled water). This solution is prepared in a 200-ml screw-cap bottle and autoclaved. One ml of this solution is added aseptically to 100 ml of culture medium.

Acetate Solution for Cultivation of Chromatiaceae

Growth yields of purple sulfur bacteria can be increased by the addition of acetate as a readily assimilated carbon source. The ammonium and magnesium salts of acetate are used to avoid strong pH changes during growth. Ammonium acetate (2.5 g) and magnesium acetate (2.5 g) are dissolved in 100 ml of distilled water and the solution is autoclaved. Standard application is 1 ml added aseptically to 100 ml of culture medium. The addition of acetate solution to media used for deep agar dilution series of Chromatiaceae is highly recommended. To liquid cultures, acetate should be added only if these are free of competing contaminants such as purple nonsulfur bacteria.

Medium 2 (Biebl and Pfennig, 1978)**Solution 1**

Distilled water	950 ml
KH ₂ PO ₄	1 g
NH ₄ Cl	0.5 g
MgSO ₄ · 7H ₂ O	0.4 g
CaCl ₂ · 2H ₂ O	0.05 g

For marine strains, 20 g of NaCl are added to solution 1 and the amount of MgSO₄ · 7H₂O is increased to 3 g.

The solution is autoclaved in the cotton-plugged 2-liter Erlenmeyer flask with an outlet near the bottom. A silicon rubber tube (about 30 cm long) with a pinchcock and a bell for aseptic distribution of the medium into bottles is connected to the outlet. A magnetic stir bar is put into the flask. When the autoclaved solution 1 is cooled to room temperature, the following sterile solutions 2 through 5 are aseptically added while magnetically stirring the medium.

Solution 2: Vitamin B₁₂ Solution

The solution is prepared as a sterile-filtered stock solution containing 2 mg of vitamin B₁₂ in 100 ml of distilled water, and 1 ml is added to solution 1.

Solution 3: Trace Element Solution SL 12

The composition is as given under Medium 1 (see above). Application is 1 ml per 1 liter of medium.

Solution 4: Sodium Bicarbonate Solution

A 5% NaHCO₃ solution is prepared in distilled water, filter-sterilized, and 30 ml are added to solution 1.

Solution 5: Sodium Sulfide Solution

A freshly autoclaved 6% solution of Na₂S · 9H₂O is prepared in distilled water, and 6 ml are added to medium.

After the mixing of solutions 1 through 5, the pH of the medium is adjusted with sterile 1M H₂SO₄ or 1M Na₂CO₃ solution to pH 7.2, and the volume brought to 1 liter with sterile distilled water, if necessary. The medium is then dispensed aseptically into sterile, 50- or 100-ml bottles with metal screw caps containing autoclavable rubber seals. A small air bubble is left in each bottle to meet possible pressure changes.

Methods for Pure Culture Isolation

Irrespective of the source of the inoculum (e.g., sample from nature, enrichment culture, or suspension of a colony), the deep agar dilution method is the most convenient method for preparing pure cultures of phototrophic sulfur bacteria (Larsen, 1952; Pfennig, 1965; Trüper, 1970; Imhoff 1988a). For the large, motile species that do not easily form colonies in agar media (e.g., *Thiospirillum jenense*) either reduced agar concentrations are applied (0.6%) or Giesberger's "Pasteur pipette" method (Giesberger, 1947) is recommended (see Pfennig and Trüper, 1992).

PREPARATION OF AGAR DILUTION SERIES For agar dilution series, selective media are not required and nonselective ones are preferred for a direct isolation without prior enrichment procedure. In a modification of the method of Pfennig (Pfennig, 1965; Trüper, 1970; Imhoff, 1988a), purified agar (thoroughly washed several times with distilled water and at a final concentration of 1.8%) is dissolved in distilled water and distributed in amounts of 3 ml into cotton-plugged test tubes. (For marine samples, 2% NaCl is added to this agar solution.) The agar is liquefied, and while kept in a hot-water bath, it is dispensed in 3-ml portions into standard test tubes, which are then plugged with cotton and autoclaved. For dilution series, the liquid agar is kept at 50°C in a water bath until use. A suitable medium is placed in the same water bath, and 6 ml of the prewarmed medium is added to each test tube. Medium and agar are mixed thoroughly by turning the tubes upside down and back, and kept at 50°C. Eight tubes are sufficient for each dilution series. The first tube is inoculated with 1–3 drops from a natural sample or enrichment culture of phototrophic bacteria; the contents are immediately mixed by inverting the tube once. Of this inoculation, 0.5–1.0 ml are then transferred into a second tube that contains the agar medium, mixed immediately by inverting as with the first tube, and so on. This dilution series is continued over eight steps. After transfer to the next tube, each tube is set into a water bath with tap water to harden the agar. After the agar has hardened, the tubes are sealed with a paraffin mixture (3 parts paraffin oil and 1 part paraffin) to prevent diffu-

sion of oxygen into the agar. Alternatively, anoxic conditions can be maintained by applying an oxygen-free gas phase. In this case, the cotton plugs are replaced by rubber stoppers after hardening of the agar. The air above the agar is replaced by gassing with sterile N₂ and 5% CO₂, and the tubes are then tightly closed with the rubber stoppers. The agar tubes are kept in the dark for several hours before they are incubated under appropriate conditions. Standard conditions routinely applied are at 20–28°C and at a light intensity of 200–1000 lux.

After cells have grown to visible colonies, the paraffin layer is removed by melting and the tubes are turned upside down on a cotton towel. Individual colonies are isolated from appropriate dilutions that shows well separated pigmented colonies. They are picked with a Pasteur pipette (the tip drawn out to a thin capillary and attached to a rubber tube). The content of the colony is suspended in 0.5 ml of sterile medium in a test tube, the suspension is microscopically checked for purity, and the whole dilution series in deep agar tubes is repeated.

In general, at least three to four such dilution series are necessary to obtain pure cultures. When pure cultures have been obtained, single colonies are inoculated into liquid medium. It is advisable to start with small-sized bottles or screw-cap tubes (10- or 25-ml) and to scale up to the regularly used sizes in following transfers of the grown culture.

CULTIVATION ON AGAR PLATES IN ANAEROBIC JARS Purple sulfur bacteria have also been successfully isolated on agar plates. A useful method for cultivating phototrophic sulfur bacteria was introduced by Irgens (1983). It is based upon the release of hydrogen sulfide, ammonia, and acetic acid from decomposing thioacetamide. The agar medium is prepared without any sulfide and poured into Petri dishes. After inoculation, these are placed in anaerobic jars (for instance, the Gas-Pak system of Becton Dickinson, Cockeysville, MD). Before the jars are closed, they are supplemented with a test tube or a small beaker containing 0.05–0.1 g of thioacetamide (depending on the size of the jar and the desired concentration) suspended in 1.0 ml of 0.2N or 0.5N HCl. The hydrogen sulfide is slowly released over a period of at least one week (Irgens, 1983). Also included in the jars are the methylene blue redox indicator and a strip of lead acetate-sulfide indicator. This method may be applied to obtain viable cell counts and was successfully used for the isolation of species of the genera *Allochromatium*, *Lamprocystis*, *Thiocapsa*, *Thiocystis* and *Ectothiorhodospira* with an illumination by a 60-W incandescent light bulb at a distance of 60 cm from the jars (Irgens,

1983). When high numbers of phototrophic bacteria are present in the sample, streaking by conventional methods is appropriate. Samples containing low numbers of phototrophic bacteria can be easily concentrated on membrane filters (e.g., cellulose acetate or cellulose nitrate).

Identification

Identification of new isolates can be obtained only by detailed studies of physiological and morphological properties together with genetic sequence data. It is not possible to identify phototrophic bacteria only from microscopic observations of natural samples or enrichment cultures. To unambiguously distinguish closely related strains and species of the same genus, often DNA-DNA hybridization studies are required.

Morphological properties obtained by microscopic techniques can provide, however, first information about cell structures (form, size and motility of the cells) and inclusions (sulfur globules, gas vesicles, and storage polymers). The cell morphology of a few representative species using light microscopy is shown in Fig. 2.

Ultrathin sections under the electron microscope reveal the fine structure of the cells, in particular, the type of the internal membrane system. The internal photosynthetic membranes are of vesicular type in most Chromatiaceae, but form tubules in some species (see Fig. 3). They carry the pigment-protein complexes of the photosynthetic apparatus.

The color of cell suspensions and absorption spectra yield preliminary information on the predominant bacteriochlorophylls and on the kind of bacteriochlorophyll-protein complexes. Photosynthetic pigments are bacteriochlorophyll α

or β and carotenoids of the spirilloxanthin, the okenone or the rhodopinal groups. In some species, tetrahydrospirilloxanthin and derivatives thereof occur. In general, the color of cultures of strains with carotenoids of the spirilloxanthin group appear orange-brown to brownish-red or pink, of those with okenone purple-red, of those with tetrahydrospirilloxanthin peach-brown, and of those with carotenoids of the rhodopinal group purple-violet. The carotenoids absorb at 480–550 nm. Absorption bands of bacteriochlorophyll α in vivo are at 380, 590–600, and 800–900 nm. Owing to the formation of different light-harvesting complexes, absorption spectra show a remarkable variation in the long wavelength range from 800–900 nm. Cultures of bacteria with bacteriochlorophyll β exhibit long wavelength absorption maxima at 980–1200 nm (Pfennig et al., 1997). Absorption spectra of whole cells are measured with cell suspensions washed twice in medium or appropriate salt solutions and then suspended in 60% sucrose solution (Biebl and Drews, 1969). Better results are often achieved by using isolated internal membranes suspended in buffer. For this purpose, it

is sufficient to break the cells by ultrasonication or with a French press and to separate whole cells and large cells fragments by centrifugation at 15,000 γ from the internal membranes, which are used for spectral measurements. Although the color and the absorption spectra give first hints to the presence of certain carotenoids, it is emphasized that a careful chemical analysis is required for identification of these compounds.

In addition to the phenotypic characterization, information on the genetic relatedness of a new isolate has to be obtained. First, information on the phylogenetic relationship can be obtained by sequences of the 16S rDNA. For the description of a new species, the determination of the G+C content of the DNA is required. When the distinction of closely related strains and species has to be achieved, also DNA-DNA hybridization studies may be necessary. The DNA base ratio, expressed as the G+C content, has been found to span a large range (from 45.5–70.4 mol%) within the Chromatiaceae. Thus, species of the genus *Chromatium*, as known before the taxonomic rearrangements proposed by Imhoff et al. (1998) had values ranging from 48.0 to 70.4 mol% (Pfennig, 1989b). Because the G+C content is a crude measure of genomic relatedness of bacteria, these values already suggested enormous diversity within the genus *Chromatium*. A phylogenetic system would be expected to group bacteria together that have much less variation in their G+C content. Indeed, after rearrangement of the species of the Chromatiaceae according to their genetic relatedness on the basis of 16S rDNA sequences (Guyoneaud et al., 1998; Imhoff et al., 1998), a quite narrow range of the G+C content is found within most of the newly established genera. This is, e.g., approx. 63–66% in the cluster, including species of *Thiocapsa*, *Lamprocystis* and *Thiolamprovum*, 69–70% in *Marichromatium* species, 64–66% in *Halochromatium* species, and 48–50% in the true *Chromatium* species. This correlation appears of such significance, that any case of high intragenetic and intraspecies variation of the G+C content necessitates experimental examination. For example, the high intraspecies variation that is noted for *Allochromatium vinosum* (61.3–66.3), *Allochromatium warmingii* (55.1–60.2), and *Thiocystis violacea* (62.8–67.9) may suggest misclassification of some of the strains. Further studies are needed to clarify the situation.

Chemotaxonomic properties such as ring structure and the isoprenoid chain length of respiratory quinones and the cell membrane fatty acid composition (which has been found to be quite helpful for identification and classification of new isolates of purple nonsulfur bacteria; Hiraishi et al., 1984; Imhoff, 1984a; Imhoff and Bias-Imhoff, 1995) are of low diagnostic value

within the Chromatiaceae. Polar lipids have been analyzed so far in only a limited number of Chromatiaceae species. First results obtained with several freshwater species showed significant correlations with their new classification, i.e., almost identical polar lipid compositions were found 1) in *Allochromatium vinosum* and *Allochromatium warmingii*, 2) in all four *Thiocystis* species and 3) in the two *Chromatium* species (J. F. Imhoff, unpublished observation). Thus, the pattern of polar lipid composition may well turn out to be a relevant property to distinguish between genera of Chromatiaceae. Because of the phylogenetic basis of the taxonomy of the Chromatiaceae, this also implies that the polar lipid composition reflects phylogenetic relations. More analytical data on Chromatiaceae are required to support this concept.

For identification of known species, the properties listed in Table 1 may be used as a guide. For the detailed description of a new bacterium, more careful studies are required, including the utilization of substrates, relation to oxygen, the ability to grow in darkness, capability of respiratory and fermentative growth, vitamin requirement, as well as ranges and optima of salt concentration, pH and temperature.

Preservation

For short- and medium-term preservation, stock cultures of purple sulfur bacteria are incubated at room temperature and a light intensity of 200–500 lux; they are grown until the initially formed elemental sulfur has just disappeared. According to Pfennig and Trüper (1992), freshly grown cultures have to be fed with 1 ml neutral sulfide solution to a final sulfide concentration of 1.5 mM and kept in the light for a few hours until the cells have formed intracellular globules of elemental sulfur. At this stage, the stock cultures can be stored in a refrigerator at 4–6°C for several months. The cultures keep well when they are put back into dim light at room temperature after 4–6 weeks of storage in the dark. Cultures with sulfur-free cells are then fed 1 ml of neutral sulfide solution and, after formation of elemental sulfur, put back into the refrigerator. Before transfer into fresh medium after 3–4 months of storage, the stock cultures are fed 1 ml of neutral sulfide solution and are transferred after the cells have formed elemental sulfur (milky appearance of the culture) and have started to grow.

For long-term storage, preservation in liquid nitrogen is recommended. Well grown cultures are supplemented with 50% dimethyl sulfoxide to give a final concentration of 5% (alternatively with a final content of 10% glycerol), thoroughly mixed, dispensed in 2-ml plastic ampules, sealed

and frozen in liquid nitrogen. Storage in liquid nitrogen is possible for many years.

Physiology

Chromatiaceae are anoxygenic phototrophic bacteria that grow photolithoautotrophically under anoxic conditions in the light using sulfide or elemental sulfur as an electron donor. Many species are also able to use molecular hydrogen and thiosulfate as electron donors under reducing culture conditions, and some use reduced iron ions (Widdel et al., 1993; Ehrenreich and Widdel, 1994). Many species are strictly anaerobic and obligately phototrophic, others are capable of chemolithoautotrophic or chemoor-ganoheterotrophic growth under microoxic to oxic conditions in the dark. Chromatiaceae are quite conservative in regard to the use of a limited number of simple organic carbon sources, of which acetate and pyruvate are the most widely used. Storage materials are polysaccharides, poly- β -hydroxybutyrate, elemental sulfur, and polyphosphate. Vitamin B₁₂ is required by several species.

We distinguish two major physiological groups of Chromatiaceae, versatile and specialized species, respectively. The specialized species depend on strictly anoxic conditions and are obligately phototrophic. Sulfide is required, and thiosulfate and hydrogen are not used as electron donors. Only acetate and pyruvate (or propionate) are photoassimilated in the presence of sulfide and CO₂. These bacteria do not grow with organic electron donors, chemotrophic growth is not possible, and sulfate is not assimilated as a sulfur source. Among these species are *Chromatium okenii*, *Chromatium weissei*, *Allochromatium warmingii*, *Isochromatium buderi*, *Thiospirillum jenense* and *Thiococcus pfennigii*.

The versatile species photoassimilate a larger variety of organic substrates. Most of them are able to grow in the absence of reduced sulfur sources with organic substrates as electron donors for photosynthesis and to assimilate sulfate as the sole sulfur source. Some species even grow chemoautotrophically or chemoheterotrophically (Gorlenko, 1974; Kondratieva et al., 1976; Kämpf and Pfennig, 1980; Kämpf and Pfennig, 1986). Among these species are *Allochromatium vinosum*, *Thiocystis violacea*, *Thiocapsa roseopersicina*, *Thiocapsa rosea*, *Thiocapsa pendens* and *Lamprobacter modestohalophilus*.

A comprehensive treatment of various aspects of the physiology of purple sulfur bacteria including structure, function and genetics of the photosynthetic apparatus is found in various chapters of *The Photosynthetic Bacteria* (Clayton and Sistrom, 1978) and *Anoxygenic Phototrophic*

Bacteria (Blankenship et al., 1995). A short overview on physiology and photosynthesis is given by Drews and Imhoff (1991). In the following, some basic principles and a few specific examples of metabolic properties of the Chromatiaceae are presented.

Energy Generation and Photosynthesis

Anoxygenic photosynthesis depends on the presence of a complex membrane-bound photosynthetic apparatus, which includes reaction center and light harvesting (antenna) pigment-protein complexes. The reaction center and antenna proteins noncovalently bind bacteriochlorophylls, carotenoids and other cofactors in stoichiometric ratios. Most purple sulfur bacteria have two antenna complexes. The complexes of the reaction center are surrounded by core antenna (a B870 or B890 antenna complex with bacteriochlorophyll α , and a B1020 complex with bacteriochlorophyll β) and mostly by additional peripheral antenna (B800–850 complexes and in a few cases also B800–820 complexes with bacteriochlorophyll α).

All purple sulfur bacteria have an internal membrane system in which the photosynthetic apparatus including reaction center and antenna complexes is integrated. These internal membranes form vesicles or tubules and are interconnected to the cytoplasmic membrane. They can be isolated by cell rupture and fractionated centrifugation. Quite characteristically, the production of photosynthetic pigments, pigment-protein complexes, and photosynthetic membrane structures is suppressed by oxygen.

The principal function of the photosynthetic apparatus is the light-mediated excitation of a bacteriochlorophyll molecule in the reaction center, followed by charge separation, and resulting in electron transfer through the membrane. At first, light is harvested by antenna pigments (bacteriochlorophylls and carotenoids bound to proteins). When light energy is transferred from the antenna complex to the reaction center, one electron per light quantum is transferred from reaction center bacteriochlorophyll to bacteriopheophytin and further to an iron-ubiquinone complex, which bridges the gap between the inner membrane surface and the reaction center. The latter is located in the membrane, towards the outer surface. From the reduced iron-ubiquinone complex, the electron enters the intramembranous ubiquinone pool together with two protons (per quinone molecule and electron) from the cytoplasm. Ubiquinone acts as a mobile carrier within the membrane. The reduced ubiquinone travels to the bc_1 complex, where the electron is donated to cytochrome c_2 , and the two protons to the

topological outside of the cell. Cytochrome c_2 acts as a mobile electron carrier between the bc_1 complex and the reaction center complex outside of the cytoplasmic membrane. In the reaction center, it replaces the missing electron donated to the iron-ubiquinone complex. The proton gradient created this way between outside and inside drives ATP synthase, thus forming ATP in the cytoplasm (for details, see Drews, 1989; Drews and Imhoff, 1991).

For the generation of reduced nicotinamide adenine dinucleotide (NADH), Chromatiaceae and other phototrophic purple bacteria require external electron donors such as reduced sulfur compounds or hydrogen. The NADH formation requires reverse electron flow, which is driven by the proton motive force provided by the cyclic photosynthetic electron flow of the light reaction mechanism described above. The electrons required for NAD^+ reduction are donated at less electronegative sites via c -type cytochromes. These electrons may derive from the oxidation of reduced sulfur compounds or molecular hydrogen.

As long as light is present, phototrophic purple bacteria are able to produce large amounts of ATP. In their natural environments, however, this is only the case during daytime. Therefore, the ability to make use of alternative mechanisms of energy conservation may be of selective advantage. Indeed, many purple sulfur bacteria not only are considerably tolerant to oxygen but also are able to perform respiratory energy transformations (Kondratieva et al., 1975; Kämpf and Pfennig, 1980).

Hydrogen Metabolism

Hydrogen serves as an excellent photosynthetic electron donor for many purple sulfur bacteria and enables these bacteria to grow photolithoautotrophically. This capability was first detected in *Allochromatium vinosum* strain D (Gaffron, 1935; Roelofsen, 1935) and later in many other purple sulfur bacteria (see Sasikala et al., 1993; Vignais et al., 1995). Hydrogen uptake is catalyzed by a reversible, membrane-bound hydrogenase, which is induced by hydrogen and independent of the nitrogen source. This membrane-bound hydrogenase is not inhibited by ammonia, but strongly inhibited by CO. During dinitrogen-fixing growth conditions, this uptake hydrogenase recycles the hydrogen produced by nitrogenase. Mutants lacking this hydrogenase demonstrate an increased hydrogen production during dinitrogen fixation (see Drews and Imhoff, 1991). The “uptake” hydrogenases of phototrophic bacteria have been studied in much detail in *Allochromatium vinosum* and *Thiocapsa roseopersicina*, and the enzymes appear to

be membrane-bound and probably contain nickel and iron-sulfur clusters. In purple bacteria, the natural electron acceptors are cytochromes of the c - or β -type (Gogotov, 1978; Gogotov, 1984; Gogotov, 1986; Vignais et al., 1985).

A great number of phototrophic purple bacteria can photoproduce hydrogen under certain growth conditions. With dinitrogen, glutamate or aspartate as nitrogen source, a number of carbon substrates (lactate, acetate, butyrate, malate and others) may be completely transformed to CO_2 and H_2 , and these in turn may serve as substrates for photoautotrophic growth (Kondratieva and Gogotov, 1983; Sasikala et al., 1993; Vignais et al., 1995).

Sulfur Metabolism

All Chromatiaceae species are capable of utilizing reduced sulfur compounds as photosynthetic electron donors. These are oxidized to sulfate as the final oxidation product. All of them oxidize sulfide and elemental sulfur, and some also oxidize thiosulfate and sulfite (Trüper, 1981a). During growth of Chromatiaceae on sulfide and thiosulfate, sulfur appears in the form of globules inside the bacterial cells. During oxidation of thiosulfate, the sulfur of these globules is entirely derived from the sulfane group of thiosulfate (Smith, 1965; Trüper and Pfennig, 1966). The sulfur in the globules exists in a metastable state and is not true elemental sulfur. It possibly consists of long chains of sulfur with polar ends either reduced (polysulfides) or oxidized (polythionates; Steudel, 1989; Steudel et al., 1990). The sulfur globules are surrounded by a protein monolayer consisting of three proteins in *Allochromatium vinosum* and two proteins in *Thiocapsa roseopersicina* (Brune, 1995a). Evidence is presented, that these sulfur globule proteins contain amino-terminal signal peptides pointing to an extracytoplasmic localization of the sulfur globules (Pattaragulwanit et al., 1998).

During aerobic dark growth, elemental sulfur may support respiration and serve as electron donor for chemolithotrophic growth (Breuker, 1964; Kämpf and Pfennig, 1986). During anaerobic dark, fermentative metabolism, intracellular sulfur serves as an electron sink during oxidation of stored carbohydrates and is reduced to sulfide (Van Gemerden, 1968b; Van Gemerden, 1968a; Van Gemerden, 1974). Though growth under these conditions is very poor in Chromatiaceae, several species have the capabilities of a fermentative metabolism that at least guarantees survival in the absence of light and oxygen (Van Gemerden, 1968a; Van Gemerden, 1968b; Krasilnikova et al., 1975; Krasilnikova, 1976; Krasilnikova et al., 1983).

Enzymatic Reactions

Intermediates in enzymatic reactions of sulfide oxidation are sulfur and sulfite. While sulfur accumulates and is clearly visible in the cells, sulfite is not observed, possibly because of its cytoplasmic formation and immediate further oxidation to sulfate (Brune, 1995b). Thiosulfate oxidation is thought to proceed through the same intermediates as sulfide oxidation. Enzymes that catalyze oxidation of reduced sulfur compounds have been intensively studied and sulfur metabolism of phototrophic bacteria has been repeatedly discussed and reviewed (Trüper and Fischer, 1982; Trüper, 1984; Trüper, 1989; Brune, 1989; 1995b).

FLAVOCYTOCHROME c Present in several Chromatiaceae, flavocytochrome c can catalyze the electron transfer from sulfide to a variety of small c -type cytochromes, such as cytochrome c -550 of *Allochromatium vinosum* (Davidson et al., 1985). The subunits of the *Allochromatium vinosum* flavocytochrome have signal peptide leader sequences that are absent from the mature protein implying that the protein is located periplasmically (Dolata et al., 1993). Though flavocytochrome c may act in sulfide oxidation of some purple sulfur bacteria, it is absent in others, which strongly suggests that alternative routes of sulfide oxidation exist.

SULFIDE QUINONE REDUCTASE A role of sulfide quinone reductase, which has been characterized from cyanobacteria and purple nonsulfur bacteria (Brune, 1995b), in sulfide oxidation of Chromatiaceae has not been established so far.

SULFITE REDUCTASE Sulfite reductase present in *Allochromatium vinosum* is suggested to catalyze the oxidation of sulfide to sulfite. The enzyme contains siroheme as prosthetic group and is present in cells grown photoautotrophically but absent in those grown photoheterotrophically (Schedel et al., 1979). A role of this enzyme was proposed not only in the oxidation of sulfide but also of polysulfide and sulfur (Trüper, 1984). DNA-based evidence exists for the wider distribution of this gene among Chromatiaceae than anticipated so far from enzymatic activities tested in these organisms (Dahl et al., 1999).

ADENOSINE-5'-PHOSPHOSULFATE REDUCTASE Adenosine-5'-phosphosulfate (APS) reductase is involved in the oxidation of sulfite to sulfate. This enzyme, forming APS from sulfite and AMP, has been found in several Chromatiaceae (Trüper and Fischer, 1982). In most cases this enzyme is membrane-bound. Apparently it is not present in

all purple sulfur bacteria and was not found, e.g., in *Marichromatium gracile* and *Marichromatium purpuratum* (Trüper and Fischer, 1982). Because APS reductase is not present in all purple sulfur bacteria, alternative enzymatic reactions for the oxidation of sulfite have to be considered.

APS can react either with phosphate to yield adenosine diphosphate (ADP) and sulfate (ADP sulfurylase) or with pyrophosphate to yield adenosine triphosphate (ATP) and sulfate (ATP sulfurylase). These reactions allow energy conservation of the high-energy phosphate bond contained in APS. The enzyme ADP sulfurylase replaces the sulfate moiety of APS by inorganic phosphate, thus producing ADP, which can be disproportionated by adenylate kinase, leading to the formation of 1 ATP and 1 AMP per 2 ADP. These reactions have been found in several Chromatiaceae species (Trüper and Fischer, 1982).

SULFITE OXIDOREDUCTASE Sulfite oxidoreductase (sulfite: acceptor oxidoreductase) is an alternative enzyme, catalyzing the oxidation of sulfite to sulfate. It has been found in almost all purple sulfur bacteria examined (Trüper, 1981a; Trüper, 1989).

Sulfur from thiosulfate, which is readily oxidized by many Chromatiaceae, most likely enters the oxidative pathway at the level of sulfur and sulfite. Enzymatic activities of thiosulfate-sulfur transferases, which split thiosulfate to elemental sulfur and sulfite, have been measured in several Chromatiaceae (Trüper, 1984). In *Allochromatium vinosum* also, a thiosulfate: acceptor oxidoreductase, which forms tetrathionate from thiosulfate was found (Smith, 1966). Tetrathionate cannot be transformed further by *Allochromatium vinosum*. In the presence of sulfide, however, tetrathionate readily reacts chemically with the sulfide to form thiosulfate and sulfur (Podgorsek and Imhoff, 1999), both of which in turn can be oxidized by *Allochromatium vinosum*.

Carbon Metabolism

In the Chromatiaceae, CO₂ is the most important carbon source. Under autotrophic growth conditions with CO₂ as sole carbon source, the Calvin cycle with ribulose biphosphate carboxylase (RubisCO) and phosphoribulokinase as key enzymes is employed (Tabita, 1995). Enzymological proof for the Calvin cycle exists for a number of species, *Allochromatium vinosum* (Fuller et al., 1961), *Chromatium okenii* (Trüper, 1964), *Thiocapsa roseopersicina* (Kondratieva et al., 1976; Zhukov, 1976), and *Thiococcus pfennigii* (Sahl and Trüper, 1977). There is little doubt, that all Chromatiaceae employ the Calvin cycle when

growing photolithoautotrophically (Kondratieva, 1979).

Already, van Niel (1931) demonstrated the stoichiometric linkage between photosynthetic carbon dioxide fixation and sulfide oxidation in phototrophic sulfur bacteria, and this relationship was experimentally confirmed for *Chromatium okenii* (Trüper, 1964). In the overall reaction, the reduction of two carbons from CO₂ to the oxidation level of carbohydrate is mediated by eight electrons derived from the oxidation of one sulfide to sulfate (Pfennig and Trüper, 1992).

The ability to use organic carbon sources is restricted to a low number of simple organic molecules in purple sulfur bacteria. A larger number of substrates is used in the more versatile species of the Chromatiaceae (e.g., *Allochromatium vinosum* and *Thiocapsa roseopersicina*) than in the specialized Chromatiaceae (e.g., *Chromatium okenii* and *Thiospirillum jenense*; Trüper, 1981b). The latter group is obligately photolithoautotrophic, but has a certain mixotrophic potential; these species strictly depend on the supply of CO₂ and sulfide, even if utilizing acetate or pyruvate. Acetate is assimilated by almost all purple sulfur bacteria.

Nitrogen Metabolism

In principle, assimilatory nitrogen and sulfur metabolism is not different from that of related nonphototrophic bacteria. Ammonia, dinitrogen, and several organic nitrogen compounds (e.g., glutamate, aspartate or yeast extract) are the most appropriate nitrogen sources of most purple sulfur bacteria.

Ammonia is used as the preferred nitrogen source by all Chromatiaceae. As in many other bacteria, it is assimilated via glutamine synthetase and glutamate synthase reactions (Brown and Herbert, 1977). Nitrate is not utilized by Chromatiaceae. The majority of purple sulfur bacteria are able to fix dinitrogen, although in some species this capability is found only in certain strains (Madigan, 1995). As dinitrogen fixation is linked to hydrogen (gas) production, this field has received much attention in research (for reviews, see Vignais et al., 1985; Haselkorn, 1986; Hallenbeck, 1987; Ludden and Roberts, 1995; Madigan, 1995). Nitrogen metabolism has been much more intensively studied in purple nonsulfur bacteria compared to purple sulfur bacteria.

Applications

Phototrophic purple sulfur bacteria have been and are being used in a number of biotechnolog-

ical processes. Most prominent examples of the application of phototrophic purple bacteria are their use in sewage treatment processes and for production of biopolymers and molecular hydrogen. Chromatiaceae have been used for the production of vitamin B₁₂ (Toohey, 1971; Koppenhagen, 1981a; Koppenhagen et al., 1981b) and biotin (Filippi and Vennes, 1971). As other phototrophic purple bacteria, they produce poly- β -hydroxybutyrate and accumulate this in considerable amounts inside their cells (Liebergesell et al., 1991; Liebergesell et al., 1992). So far, no use has been made of the wide spectrum of colorful carotenoids produced by purple sulfur bacteria.

They have the potential to be used specifically for the removal of sulfide and for sulfur production from H₂S-containing fluids and gases, though applications for such processes have not been reported.

The use of phototrophic sulfur bacteria in large-scale processes has the advantages that light is a clean energy source and oxygen is not required. However, the advantage of avoiding problems with oxygen supply, which is necessary for aerobic bacteria, is replaced by the disadvantage caused by the problems of supplying sufficient light. This is at least a problem in the lower latitudes and in regions with irregular periods of sunshine, because considerable efforts have to be made for artificial illumination. Under these circumstances, the high expenditure of energy and money considerably lowers the possible commercial acceptance of such processes.

Waste Water Treatment

Phototrophic bacteria are regularly found in conventional sewage treatment plants, and though the facultative chemotrophic purple nonsulfur bacteria compete best under such conditions, purple sulfur bacteria always are present and under certain conditions form the dominant group (Holm and Vennes, 1971; Siefert et al., 1978).

Liquid wastes from food industries or communities often are fed into shallow open lagoons, which is a quite simple, but effective treatment system. Studies of such system have repeatedly shown the abundance of phototrophic sulfur bacteria: *Thiopedia rosea* in animal-fat-rendering waste, Chromatiaceae in petroleum refinery waste (Cooper, 1963; Cooper, 1965; Cooper et al., 1975), Chromatiaceae in municipal sewage (May and Stahl, 1967), *Thiocapsa roseopersicina* and *Allochromatium vinosum* in potato waste (Holm and Vennes, 1970), *Thiopedia rosea* in feedlot manure (Wenke and Vogt, 1981), and *Thiocapsa roseopersicina* in sugar factory efflu-

ents (N. Pfennig and H.G. Trüper, unpublished observations).

An advanced system using phototrophic bacteria in the purification of municipal and industrial wastewater is that developed by M. Kobayashi and coworkers working with mixed natural enrichments of phototrophic sulfur and nonsulfur bacteria (Kobayashi et al., 1971; Kobayashi and Tchan, 1973; Kobayashi, 1977; Kobayashi and Kobayashi, 1995). In addition to the organic solute and sulfide contents of a variety of sewages, phototrophic bacteria completely removed bad-smelling substances, such as putrescine, cadaverine, and mercaptans, as well as the carcinogen dimethylnitrosamine (Kobayashi and Tchan, 1978).

These authors also took advantage of the biomass produced by the phototrophic bacteria, which is a valuable source of animal feed owing to its rich content in vitamins and in essential and sulfur-containing amino acids (Vrati, 1984). It has been used in plankton production, in the culture of shrimp, and as food for fish and chicken (Kobayashi, 1977; Mitsui, 1979). Addition of phototrophic bacterial cells to the food increased the survival of fish as well as the production and quality of hens' eggs (Kobayashi and Tchan, 1973). With similar success, the cell biomass of phototrophic bacteria has been used as fertilizer in agriculture (Kobayashi and Tchan, 1973).

Hydrogen Production

Under nitrogen starvation, almost all phototrophic bacteria are able to produce molecular hydrogen. This process is mainly due to hydrogen evolution from nitrogenase. A large number of substrates has been used by different research groups and with different purple bacteria to produce hydrogen (see Kumazawa and Mitsui, 1982; Cooper, 1963; Sasikala et al., 1993). Though most of this work has taken advantage of the purple nonsulfur bacteria, also purple sulfur bacteria were included in these studies (Mitsui, 1975, 1979). Bolliger et al. (1985) developed a system to produce hydrogen gas by phototrophic bacteria growing in sugar-refinery wastewater. Even purified and immobilized hydrogenase of *Thiocapsa roseopersicina* has been used for hydrogen production in biofuel cells (Yarapolov et al., 1982).

Acknowledgment. The calculations for and the preparation of phylogenetic trees by Dr. J. Söling (Institut für Meereskunde an der Universität Kiel, Germany) is kindly acknowledged.

The Family Ectothiorhodospiraceae

JOHANNES F. IMHOFF

Phylogeny

Separate phylogenetic lineages are represented by the purple sulfur bacteria belonging to the γ -Proteobacteria (Chromatiaceae and Ectothiorhodospiraceae) and by the purple nonsulfur bacteria, belonging to the α -Proteobacteria and β -Proteobacteria.

Ectothiorhodospiraceae represent halophilic and alkaliphilic purple sulfur bacteria that form a separate lineage of phylogenetic descent related to the Chromatiaceae, as was first demonstrated by analysis of rRNA oligonucleotide catalogues (Stackebrandt et al., 1984). In a phylogenetic tree based on 16S rDNA sequences, both families form distinct groups within the γ -Proteobacteria (Imhoff and Siling, 1996).

The salt requirement not only is a characteristic property of all Ectothiorhodospiraceae, but also distinguishes moderately and extremely halophilic *Halorhodospira* species from slightly halophilic *Ectothiorhodospira* and *Thiorhodospira* species. Two clearly distinct phylogenetic lineages within the Ectothiorhodospiraceae separate the slightly halophilic and marine species from the moderately to extremely halophilic species (see Fig. 1).

Correlation between salt relations and phylogenetic position of the purple sulfur bacteria point out the phylogenetic and taxonomic importance of salt requirement and salt dependence, which also distinguishes major phylogenetic groups of the Chromatiaceae (Imhoff et al., 1998b) and genera of the purple nonsulfur bacteria such as *Rhodobacter* and *Rhodovulum* (Hiraishi and Ueda, 1994) and others (Imhoff et al., 1998a). At present, *Arhodomonas aquaeolei* is the only nonphototrophic, purely chemotrophic representative in this lineage, which is closely related to *Halorhodospira* species (Adkins et al., 1993; Imhoff and Siling, 1996).

Taxonomy

Ectothiorhodospiraceae

The taxonomic position of the Ectothiorhodospiraceae has been disputed since their discovery by Pelsh, 1936. He distinguished phototrophic purple sulfur bacteria that deposit elemental sulfur globules outside the cells, which he called "Ectothiorhodaceae," from those with elemental sulfur inside their cells, which he called "Endothiorhodaceae" (Pelsh, 1937). Pelsh's isolates were lost, but *Ectothiorhodospira mobilis* was reisolated (Truper, 1968), and the genus *Ectothiorhodospira* included into the Chromatiaceae (Pfennig and Truper, 1971) because of the ability to perform an oxidative dissimilatory sulfur metabolism similar to other phototrophic purple sulfur bacteria. Later, a clear differentiation of *Ectothiorhodospira* species from Chromatiaceae was demonstrated by oligonucleotide patterns of 16S rRNA molecules (Stackebrandt et al., 1984), substantiated by 16S rDNA sequence analyses (Imhoff and Siling, 1996), and a separation of the Ectothiorhodospiraceae as a family distinct from the Chromatiaceae was proposed (Imhoff, 1984a). The complete sequence analysis of the 16S rDNA from a large number of strains including all available type strains of *Ectothiorhodospira* and *Halorhodospira* not only supported their separation from the Chromatiaceae but also demonstrated the divergence of two groups within this family (Imhoff and Siling, 1996). Because of the large phylogenetic distance between these two groups, the extremely halophilic species were transferred to the new genus *Halorhodospira* (Imhoff and Siling, 1996). The separation of the two genera of Ectothiorhodospiraceae is supported by a number of physiological properties and chemotaxonomic characteristics. Studies on DNA-DNA and rRNA-DNA hybridization (Ivanova

Fig. 1. Phylogenetic relatedness of the Ectothiorhodospiraceae derived from 16S rDNA sequences (Imhoff and Süling, 1996; Bryantseva et al., 1999).

et al., 1985), analysis of lipopolysaccharides (Zahr et al., 1992), DNA restriction patterns (Ventura et al., 1993), as well as lipid, fatty acid and quinone composition (Imhoff et al., 1982; Imhoff 1984b; Thiemann and Imhoff, 1996; Tindall, 1980; Ventura et al., 1993; see Imhoff and Bias-Imhoff, 1995) support the phylogenetic and taxonomic relations within the Ectothiorhodospiraceae. The taxonomy of Ectothiorhodospiraceae is in accord with their phylogenetic relationships based on 16S rDNA sequences.

Ectothiorhodospira and *Halorhodospira* species are rods, most often slightly bent rods, vibrios or spirilla that during oxidation of sulfide produce elemental sulfur which is deposited outside the cells (Fig. 3, Tables 2 and 3). Only one species, *Ectothiorhodospira vacuolata*, is known to produce gas vesicles (Fig. 4). All of the phototrophic Ectothiorhodospiraceae produce characteristic internal membrane stacks that may constitute a large fraction of the internal volume of these cells (Figs. 5 and 6).

In recent years two new bacteria have been described which are phylogenetically related to the Ectothiorhodospiraceae. *Arhodomonas aquaeolei* is a moderately halophilic, strictly chemotrophic bacterium that is distantly related to *Halorhodospira* species, but clearly clusters with the branch of moderately and extremely halophilic bacteria of this family (Adkins et al., 1993; Imhoff and Süling, 1996). *Thiorhodospira sibirica* is a strictly phototrophic bacterium phylogenetically related to *Ectothiorhodospira* species and belonging to the branch of slightly halophilic Ectothiorhodospiraceae (Bryantseva et al., 1999; Fig. 1). It is unique in depositing elemental sulfur not only outside the cells but also in the peripheral part of the cells. Diagnostic properties of the genera *Ectothiorhodospira*,

moderately high salt concentrations. Growth is dependent on saline and alkaline conditions. All species of this genus are rods or spirals, motile by a polar tuft of flagella, have internal photosynthetic membranes as lamellar stacks (Cherni et al., 1969; Holt et al., 1968; Imhoff et al., 1981; Imhoff and Süling, 1996; Remsen et al., 1968; Oren et al., 1989), and contain menaquinone with 7 isoprene units (MK-7) together with ubiquinones Q-7 or Q-8 (Imhoff and Bias-Imhoff, 1995).

Analyses of 16S rDNA sequences and fatty acid composition supported the identification and species assignment of some strains, but demonstrated misclassification of others (Thiemann and Imhoff, 1996; Imhoff and Süling, 1996). The close relationship between *Ect. shaposhnikovii* and *Ect. vacuolata* that was demonstrated already by DNA-DNA hybridization studies (Ivanova et al., 1985) was supported. Several strains which previously had been tentatively

identified as *Ectothiorhodospira mobilis* formed a separate cluster on the basis of their 16S rDNA sequences and were recognized as two new species. *Ectothiorhodospira haloalkaliphila* includes the most alkaliphilic strains originating from strongly alkaline soda lakes, strain 51/7 (BN 9903, ATCC 51935) and C (BN 9902, Imhoff et al., 1978). In particular, strain BN 9903 (ATCC 51935) has been intensively studied (Imhoff et al., 1982; Imhoff, 1984b; Imhoff and Riedel, 1989; Imhoff and Thiemann, 1991; Imhoff et al., 1991; Stackebrandt et al., 1984; Zahr et al., 1992; Ventura et al., 1993) and it is now quite clear that this strain does not belong to *Ect. mobilis* (Imhoff and Süling, 1996). *Ectothiorhodospira marina* is represented by isolates from the marine environment (strain BA 1010, DSM 241; Matheron and Baulaigue, 1972). Another isolate, strain BA 1011 (Matheron and Baulaigue, 1972) was most similar to strain BA 1010, but due to the lack of sufficient evidence its identification on the species level to strain BA 1010 was kept open (Imhoff and Süling, 1996).

Quite a number of strains were confirmed as strains of *Ect. mobilis*, namely strains 8112 (DSM 237), 8113 (DSM 238), and 8815 (DSM 240, Trüper, 1970; Mandel et al., 1971). Others that were tentatively assigned to this species were not identical with *Ect. mobilis*. Strain 8115 (DSM 239, Trüper, 1970; Mandel et al., 1971) was recognized as belonging to *Ect. shaposhnikovii*, as supported by DNA-DNA hybridization studies (Ivanova et al., 1985).

Presently known species of this genus are *Ect. mobilis*, *Ect. marismortui*, *Ect. marina*, *Ect. haloalkaliphila*, *Ect. shaposhnikovii* and *Ect. vacuolata*. Diagnostic properties of these species are shown in Table 2.

Halorhodospira

This genus represents moderately and extremely halophilic species that were removed from the genus *Ectothiorhodospira* (Imhoff and Süling, 1996). All *Halorhodospira* species are vibrioid or spirals, motile by bipolar flagella and have internal photosynthetic membranes as lamellar stacks (Imhoff and Süling, 1996; Imhoff and Trüper, 1977, 1981; Raymond and Sistrom, 1967, 1969). Growth is dependent on highly saline and alkaline conditions.

In agar media, red- or green-colored colonies are formed. Photosynthetic pigments of the red-colored species are bacteriochlorophyll *a* and carotenoids of the normal spirilloxanthin series, with spirilloxanthin as the predominant component (Schmidt and Trüper, 1971; Schmidt, 1978). The green-colored species, *Hlr. halochloris* and *Hlr. abdelmalekii*, contain bacteriochlorophyll *b* esterified with Δ -2,10-phytyadienol, not with phytol as in the bacteriochlorophyll *a* of *Hlr. halophila* (Steiner et al., 1981; Steiner, R., personal communication). The carotenoid content of *Hlr. halochloris* and *Hlr. abdelmalekii* is low. The carotenoid composition of both of these species is quite similar. Mainly methoxyrhodopin glucoside (major), rhodopin glucoside, and rhodopin have been found in *Hlr. halochloris* (Schmidt, K., personal communication). Absorption spectra of living cells or chromatophore suspensions allow the identification of the bacteriochlorophyll present and provide some information on the types of carotenoids (Fig. 2).

Presently known species of this genus are *Halorhodospira halophila*, *Halorhodospira halochloris* and *Halorhodospira abdelmalekii*.

Diagnostic properties of *Halorhodospira* species are shown in Table 3.

Thiorhodospira

A new phototrophic sulfur bacterium isolated from a Siberian soda lake, *Thiorhodospira sibirica*, has been shown to be genetically related to the genus *Ectothiorhodospira* and many of its properties resemble those of *Ectothiorhodospira* species (Bryantseva et al., 1999). During photolithoautotrophic growth with sulfide as electron donor, the impressively large bacterium forms elemental sulfur globules outside as well as inside the cells. Upon careful microscopic inspection, it can be realized that the sulfur globules associated with the cells are located in the periphery that is represented by an apparently large periplasmic space, but not in the cell interior. Therefore, the mechanism of elemental sulfur formation and the location of the involved

enzymes appear to be the same as in species of other *Ectothiorhodospiraceae*.

In the presence of sulfide, organic substances are photoassimilated. Cells are vibrioid or spiral and motile by a monopolar flagellar tuft. Internal photosynthetic membranes are parallel lamellae underlying the cytoplasmic membrane. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spirilloxanthin series. Development is dependent on sodium salts in low concentrations and on alkaline conditions. The metabolism is strictly anaerobic and obligately phototrophic.

Arhodomonas

Arhodomonas aquaeolei has been found to be genetically related to the *Ectothiorhodospiraceae* and in particular to *Halorhodospira* species (Adkins et al., 1993; Imhoff and Süling, 1996). It is the first halophilic and strictly

chemotrophic bacterium that is a close relative to the otherwise phototrophic Ectothiorhodospiraceae and has a restricted spectrum of carbon sources used for growth. Primarily due to its genetic relationship based on the 16S rDNA sequence, it is considered as a member of the Ectothiorhodospiraceae.

Habitats

Like other phototrophic sulfur bacteria, phototrophic Ectothiorhodospiraceae (the strictly chemotrophic *Arhodomonas* is not considered here) develop under anoxic conditions, if soluble sulfide, light and bicarbonate are available. Accordingly they inhabit anoxic environments with sulfide and light. Phototrophic Ectothiorhodospiraceae are found in alkaline environments with saline or hypersaline conditions. The salt requirement of species belonging to the phylogenetic lineage of *Ectothiorhodospira* and *Thiorhodospira* is low and characteristic of bacteria from brackish and marine environments. A requirement for moderate to extreme salt concentrations specifies bacteria of the lineage with *Halorhodospira* [and *Arhodomonas*] species. Their requirement for and the tolerance of salt and alkaline pH is the physiological prerequisite to inhabit soda lakes and alkaline brines,

which are the natural habitats to which these bacteria are specifically adapted. Apparently, ecological aspects and adaptation of bacteria to specific factors of their natural environment are of importance in phylogeny and taxonomy (Fig. 1). Distinct phylogenetic lineages are expected to result from the evolution in separate habitats that, due to their outstanding properties, allow the development of specifically adapted bacteria only. Such outstanding properties are e.g., extreme conditions of salt concentration, temperature and pH.

Phototrophic species of the Ectothiorhodospiraceae were isolated from marine sources, estuaries, salt flats, salt lakes, and soda lakes from many parts of the world (Grant et al., 1979; Imhoff and Trüper, 1976, 1977, 1981; Imhoff et al., 1978, 1979, 1981; Matheron and Baulaigue, 1972; Pelsh, 1936; Raymond and Sistrom, 1967; Tew, 1966; Tindall, 1980; Trüper, 1968, 1970; Ventura et al., 1988; see Imhoff, 1988b). Occasionally, certain *Ectothiorhodospira* species may be found in soil.

Highly saline and alkaline soda lakes show a natural abundance of *Halorhodospira* species (Jannasch, 1957; Imhoff et al., 1978, 1979; Imhoff, 1988b), which can be taken as proof of their successful adaptation to these environments. Because of their mass development, these bacteria may cause red or green coloration of their

Fig. 7. Shallow shore line of a soda lake in the Wadi Natrun (Egypt) with massive development of *Hlr. halophila* causing intense red coloration.

habitats. Shallow parts of soda lakes in the Wadi Natrun may be intensively red colored, due to the development of *Hlr. halophila* (Fig. 7). Small puddles of such locations may show separate development of green- and red-colored species of *Halorhodospira* (Fig. 8). Also top layers of the sediments of Wadi Natrun lakes demonstrated separate layers of the green-colored and the red-colored *Halorhodospira* species (Fig. 9). *Hlr. abdelmalekii*, *Hlr. halochloris*, and in particular *Hlr. halophila* are among the most halophilic phototrophic bacteria (see Imhoff, 1988b). Isolates of *Hlr. halophila* from soda lakes in the Wadi Natrun (Egypt), which have salt optima of 25% total salts and can grow in saturated salt solutions, are the most halophilic and halotolerant eubacteria.

Ectothiorhodospira marismortui was isolated from a hypersaline sulfur spring on the shore of the Dead Sea (Oren et al., 1989). The spring water was characterized by high salinity (approx. 17%), high sulfide content (approx. 2.5 mM), nearly 40°C and a pH around 5.2. The isolate grew poorly at pH 5.5 but showed optimal development between pH 7 and 8 (Oren et al., 1989). *Thiorhodospira sibirica* was found in microbial

Fig. 8. Soda Lake Muluk in the Wadi Natrun (Egypt), which was almost dry due to falling water level in the area. Distinct red- and green-colored puddles can be seen, in which red- and green-colored species of the genus *Halorhodospira* predominate, and have been isolated (Imhoff et al., 1979).

Fig. 9. Separate development of green-colored and red-colored *Halorhodospira* species within the top layers of a sediment of an alkaline soda lake of the Wadi Natrun (Egypt), the green species being on top.

films formed on the sediment surface or on decaying plant material in the littoral of Siberian soda lakes with low salinity (0.2–1%) and alkaline pH (pH 9.2–9.7; Bryantseva et al., 1999).

Isolation

Selective Enrichment

Marine strains of *Ectothiorhodospira* have been selectively enriched under photoautotrophic conditions in modified Pfennig's medium (Pfennig, 1965; Trüper, 1970; Pfennig and Trüper, 1992) with sulfide as an electron donor, and under saline and alkaline conditions (3% NaCl and pH 7.6 to 8.5), even in the presence of high numbers of marine Chromatiaceae in the natural sample (Trüper and Imhoff, 1981).

For the extremely halophilic *Halorhodospira* species, the dependence on and the tolerance of

high salinity and alkalinity are strongly selective conditions for their enrichment. Many *Halorhodospira* strains have been isolated from various locations using a medium [HSE (Highly Saline Ectothiorhodospiraceae) medium] based on the mineral salt composition of the soda lakes of the Wadi Natrun (Jannasch, 1957; Imhoff and Trüper, 1977; Imhoff et al., 1979; Imhoff, 1988a) and modifications thereof. Depending on the species composition of the sample and the salt concentration of the media, various Ectothiorhodospiraceae will develop.

For enrichment, environmental samples are inoculated into suitable media in 20-ml screw-cap test tubes or 50-ml bottles, which are completely filled with the medium. They are incubated at the desired temperature and under illumination of an incandescent lamp at 1,000 to 10,000 lux.

Isolation Procedures

Preparation of Agar Dilution Series. For isolation, agar dilution series are prepared either with enrichment cultures or with promising natural samples by direct inoculation from the environment. Media used for direct isolation without prior enrichment does not need to be selective.

In a modification of the method of Pfennig (Pfennig 1965; Trüper, 1970), purified agar is dissolved (1.8%) in distilled water and distributed in amounts of 3 ml into cotton-plugged test tubes. The agar is sterilized by autoclaving. The liquid agar is kept at 50°C in a water bath until used. A suitable medium is placed in the same water bath, and 6 ml of the pre-warmed medium is added to each test tube. Medium and agar are mixed thoroughly by turning the tubes upside down and back, and kept at 50°C. Six to eight tubes are sufficient for each dilution series. The first tube is inoculated with a natural sample or enrichment culture and mixed carefully; approximately 0.5 to 1.0 ml is transferred to a second tube, mixed carefully, and the procedure continued up to the last tube. The tubes are immediately placed into a cold water bath until the agar has hardened, then they are sealed with a paraffin mixture (3 parts paraffin oil and 1 part paraffin) and kept in the dark for several hours before illumination with approx. 500 to 2000 lux. After cells have grown to visible colonies, the paraffin layer is removed by melting, and well-separated colonies are picked with a Pasteur pipette (the tip drawn out to a thin capillary) and transferred to a second dilution series. In general, three to four such dilution series are necessary to obtain pure cultures. When pure cultures have been obtained, single colonies are inoculated into liquid medium.

Isolation on Agar Plates. A convenient method for growing phototrophic sulfur bacteria on agar plates has been described by Irgens, 1983. Media without added sulfide are used with the GasPak system (Becton Dickinson and Co., Cockeysville, MD). As a source of sulfide, a test tube with 0.05 to 0.1 g of thioacetamide and 1 ml of 0.5 N HCl is placed in the anaerobic jar. Thioacetamide slowly decomposes in acid to ammonia, hydrogen sulfide, and acetic acid. The H₂S gas is released over a period of at least one week. As indicators, methylene blue (for oxygen) and a strip with lead acetate (for H₂S) are included. This method also can be used conveniently to assay viable counts of purple sulfur bacteria. It has been used successfully for the isolation of species of the genera *Pfennigia*, *Allochroomatium*, *Lamprocystis*, *Thiocapsa*, *Thiocystis*, and *Ectothiorhodospira* (Irgens, 1983).

Media for *Ectothiorhodospira* Species

Enrichment and subsequent isolation of *Ect. mobilis*, *Ect. shaposhnikovii* and *Ect. marina* have been achieved by using Pfennig's medium for purple sulfur bacteria with 3% NaCl at alkaline pH 7.6–8.5 (Pfennig, 1965; Trüper, 1970; Matheron and Baulaigue, 1972). This medium apparently supports growth of all *Ectothiorhodospira* species including *Ect. marismortui* (Thiemann and Imhoff, 1996). It is not suitable for the extremely halophilic species *Hlr. halochloris*, *Hlr. halophila*, and *Hlr. abdelmalekii*. A strongly alkaline medium that is used for *Halorhodospira* species (HSE medium), at salt concentrations of 3–5% also supports growth of several *Ectothiorhodospira* species, namely *Ect. haloalkaliphila*, *Ect. vacuolata* and *Ect. shaposhnikovii*, but not of *Ect. mobilis*, *Ect. marismortui* and *Ect. marina* (Thiemann and Imhoff, 1996; Table 2).

HSE (Highly Saline Ectothiorhodospiraceae) Medium for *Halorhodospira* Species

An alkaline and highly saline medium based on the mineral salts composition of the soda lakes of the Wadi Natrun has been used for isolation of *Ectothiorhodospira* and *Halorhodospira* strains from various environments (Imhoff and Trüper, 1977, 1981; Imhoff et al., 1978, 1981). This medium is well suited for isolation and cultivation of all *Halorhodospira* species and several *Ectothiorhodospira* species. It is buffered by bicarbonate (200 mM, pH 9.0) and adjusted to the desired salinity by changing the concentration of NaCl. Also the type strain of *Hlr. halophila*, SL1, (Raymond and Sistrom, 1967) grows well in this medium. The mineral salts composi-

tion of this medium (Imhoff and Trüper, 1977) and its preparation as recommended for standard cultivation procedures is as given below (see Imhoff, 1988a).

The basal medium has the following composition (for a medium with 15% salinity, per liter):

KH ₂ PO ₄	0.8 g
Na acetate	2.0 g
Na ₂ S ₂ O ₃ · 15H ₂ O	1.0 g
NaCl	130.0 g
1 M Na carbonate, pH 9.0	200.0 ml
Trace element solution SLA (see below)	1 ml

The components are dissolved in 600 ml of distilled water and the carbonate buffer is added. The volume is brought to 980 ml and the solution is autoclaved. The salinity is adjusted to the desired value by variation of the NaCl content (assuming a contribution of 2% by the other medium constituents). The final pH is 9.0.

The following salt solutions are autoclaved separately and, after cooling, they are added with gentle stirring.

2% MgCl ₂ · 7H ₂ O	5 ml/liter
1% CaCl ₂ · 2H ₂ O	5 ml/liter
5% Na ₂ S · 9H ₂ O	5–10 ml/liter
20% NH ₄ Cl	4 ml/liter

The medium is immediately dispensed into sterilized culture vessels, which are filled with medium except for a small air bubble. The vessels are incubated at the desired incubation temperature (33–400°C) prior to inoculation to achieve volume expansion and then 10% of the medium is replaced by a fresh preculture.

For *Halorhodospira halophila* and most *Ectothiorhodospira* species, thiosulfate is a suitable additional electron donor that makes feeding with sulfide unnecessary. Thiosulfate can be omitted in media for species that do not use thiosulfate, such as the green-colored *Halorhodospira* species. Acetate is a suitable carbon source for all species and increases the cell yield of the cultures.

Trace element solution SLA (Imhoff and Trüper, 1977)

FeCl ₂ · 4H ₂ O	1.800 mg
CoCl ₂ · 6H ₂ O	250 mg
NiCl ₂ · 6H ₂ O	10 mg
CuCl ₂ · 2H ₂ O	10 mg
MnCl ₂ · 4H ₂ O	70 mg
ZnCl ₂	100 mg
H ₃ BO ₃	500 mg
Na ₂ MoO ₄ · 2H ₂ O	30 mg
Na ₂ SeO ₃ · 5H ₂ O	10 mg

The salts are dissolved separately in a total of 900 ml of double-distilled water; the solutions are mixed, the pH is adjusted to 2–3 with 1 N HCl, and the final volume is brought to 1 liter.

Cultivation

In general, cultivation of *Ectothiorhodospira* species is possible in any size of bottle and glass

fermenter as long as illumination is sufficient and temperature is controlled. For routine cultivation 50-ml or 100-ml bottles appear the most suitable size. Because of the problems of self-shading of the cells, even for growth of larger cell masses round 1-liter bottles are very well suited. Cultures are incubated at 1,000 to 20,000 lux (approximately 100 to 2,000 foot candles) and at temperatures between 33 and 40°C. The pH optima found with different strains and species (and also in different media) are between 7.4 and 9.1. Salt optima of the different species are shown in Tables 2 and 3. For routine cultivation, the HSE medium is used at salinities of 15% for *Hlr. abdelmalekii*, *Hlr. halochloris*, and some strains of *Hlr. halophila* (including the type strain), of 25% for the most halophilic strains of *Hlr. halophila*, of 5% for *Ect. haloalkaliphila* and of 2–3% for *Ect. shaposhnikovii* and *Ect. vacuolata*. Other *Ectothiorhodospira* species are routinely grown with modified Pfennig's medium containing 3% NaCl.

Identification

Ectothiorhodospiraceae (Imhoff, 1984a) are halophilic phototrophic purple sulfur bacteria that, during oxidation of sulfide, deposit elemental sulfur microscopically visible outside or in the peripheral, periplasmic part of their cells. They are distinguished from the Chromatiaceae by lamellar internal membrane structures and by the dependence on saline and alkaline growth conditions (Imhoff, 1989). *Ectothiorhodospiraceae* have a characteristic composition of polar lipids (Asselineau and Trüper, 1982; Imhoff et al., 1982), fatty acids (Thiemann and Imhoff, 1996) and quinones (Imhoff, 1984b; Ventura et al., 1993), which distinguishes this group from Chromatiaceae and purple nonsulfur bacteria (Imhoff and Bias-Imhoff, 1995).

While *Halorhodospira* species are extremely halophilic bacteria and do not grow below 10% total salts, *Ectothiorhodospira* species have growth optima well below 10%. Differentiation of *Halorhodospira* and *Ectothiorhodospira* species is possible on the basis of significant differences of 16S rDNA sequences (similarities of less than 90%) and characteristic signature sequences (Imhoff and Süling, 1996; Fig. 1). In addition, fatty acid and major quinone components are different in species of both genera (Thiemann and Imhoff, 1996). *Ectothiorhodospira* species have MK-7 and either Q-7 or Q-8 as major components, whereas *Halorhodospira* species do not contain significant proportions of homologs with 7 isoprenoid units, but have MK-8 and Q-8 together with a short chain MK as major components (Imhoff 1984b; Ventura et al.,

1993). Both genera also form separate groups according to their fatty acid composition (Thiemann and Imhoff 1996; Imhoff and Söling, 1996). Properties for identification of *Ectothiorhodospira* and *Halorhodospira* species are shown in Tables 2 and 3, respectively.

For identification and verification of new isolates of Ectothiorhodospiraceae, the comparison with type strains of these bacteria deposited in and available from culture collections such as the American Type Culture Collection (ATCC in Rockville, MD) and the Deutsche Sammlung von Mikroorganismen und Zellkulturen (DSMZ in Braunschweig, Germany) is necessary. The majority of types and other strains of Ectothiorhodospiraceae (and other anoxygenic phototrophic bacteria) also is available from a culture collection maintained by the author. The type strains are: *Ect. mobilis* (DSM 237), *Ect. marismortui* (DSM 4180), *Ect. shaposhnikovii* (DSM 243), *Ect. vacuolata* (ATCC 43036, DSM 2111), *Ect. haloalkaliphila* (ATCC 51935), *Ect. marina* (DSM 241), *Hlr. halophila* (DSM 244), *Hlr. halochloris* (ATCC 35916), *Hlr. abdelmalekii* (ATCC 35917), and *Thiorhodospira sibirica* (ATCC 700588).

Preservation

For short-term preservation, well-grown cultures may be kept in closed, air-tight screw-cap bottles at 4°C in a refrigerator or at room temperature for several months, even years. Cultures of *Hlr. halochloris* and *Hlr. abdelmalekii* lose viability much faster than do cultures of other Ectothiorhodospiraceae. Strains of *Ect. mobilis* and *Hlr. halophila*, however, have been kept on a laboratory desk (room temperature and dim light) for five years and still contained numerous viable cells that grew readily after transfer into fresh medium. Maintenance transfer of liquid cultures should occur at intervals of not more than 6 months.

For long-term storage, preservation in liquid nitrogen is recommended. Well-grown cultures are supplemented with 50% dimethyl sulfoxide to give a final concentration of 5%, thoroughly mixed, dispensed in plastic ampoules, sealed and frozen in liquid nitrogen. Good viability has been demonstrated with several strains after more than 20 years.

Physiology

All species of *Ectothiorhodospira*, *Halorhodospira* and *Thiorhodospira* grow well under anaerobic conditions in the light with reduced

sulfur compounds as photosynthetic electron donors, either photoautotrophically or photoheterotrophically with a number of organic compounds and inorganic carbonate. Some species, e.g., *Ect. shaposhnikovii* and *Ect. haloalkaliphila* grow microaerobically to aerobically in the dark. Growth factors are not required, but vitamin B₁₂ enhances growth of some strains.

During phototrophic growth with sulfide as an electron donor, sulfide is first oxidized to elemental sulfur which is then oxidized to sulfate, as has been shown for *Ect. mobilis* (see Trüper, 1978). Elemental sulfur is deposited outside the cells. Under alkaline growth conditions that are favorable for *Ectothiorhodospira* species, polysulfides are stable intermediates in sulfide oxidation. As a result, polysulfides are the first measurable oxidation products, and the medium becomes yellow-translucent at this stage. After sulfide depletion, elemental sulfur droplets are rapidly formed and the medium becomes cloudy to opaque. During further growth, cultures of red-colored species become pinkish and finally red if elemental sulfur disappears. These color changes are best observed under photoautotrophic growth conditions. Aspects of sulfur metabolism of *Ectothiorhodospira* and *Halorhodospira* species are summarized (Trüper, 1978; Trüper and Fischer, 1982).

Under autotrophic growth conditions, the fixation of carbon dioxide via the Calvin cycle is the major route of carbon assimilation in *Ect. shaposhnikovii* and high activities of ribulose-bisphosphate carboxylase have been found in this species (Firsov et al., 1974), as well as in *Ect. mobilis* (Sahl and Trüper, 1977) and *Hlr. halophila* (Tabita and McFadden, 1972). Under photoheterotrophic growth conditions, considerable proportions of cellular carbon are derived from carbon dioxide, which is assimilated by pathways not involving the Calvin cycle. The assimilation of several organic carbon sources (such as acetate and propionate) depends on the presence of carbon dioxide and proceeds via carboxylation reactions (Firsov and Ivanovsky, 1974, 1975). Phosphoenolpyruvate carboxylase, ferredoxin-dependent pyruvate synthase, and oxoglutarate synthase were found in *Ect. shaposhnikovii* (Firsov et al., 1974); phosphoenolpyruvate carboxylase, phosphoenolpyruvate carboxykinase, and pyruvate carboxylase were found in *Ect. mobilis* (Sahl and Trüper, 1977). All enzymes of the glycolytic pathway and the tricarboxylic acid cycle, with the exception of oxoglutarate dehydrogenase, are present in *Ect. shaposhnikovii* (Krasilnikova, 1975). Cells grown on acetate had increased activities of isocitrate lyase, indicative of the function of the glyoxylic acid pathway. While poly- β -hydroxybutyric acid is the principal carbon reserve material in the absence of carbon

dioxide, in its presence, carbohydrates are preferentially formed from acetate and butyrate as well as from other carbon sources (Novikova, 1971).

Salt adaptation

The circumscription of bacterial salt relations uses the salt concentration at which optimum growth occurs and defines nonhalophilic bacteria (below 0.1 M NaCl), brackish water bacteria (approx. 0.1–0.3 M NaCl), marine or slightly halophilic bacteria (approx. 0.4–1.0 M NaCl), moderately halophilic bacteria (approx. 1.0–2.0 M NaCl) and extremely halophilic bacteria (more than 2.0 M NaCl; Imhoff, 1993). Bacteria of each of these groups may show up with different degrees of salt tolerance. Even nonhalophilic bacteria may exhibit extreme salt tolerances and grow at very high concentration, though at a sub-optimal level. To adapt to high concentrations of salts and to cope with the high external osmotic pressure, bacteria and other unicellular microorganisms have to accumulate osmotic active molecules, so-called compatible solutes or osmotica, that are compatible with the molecular cell structures and metabolic processes (see Imhoff, 1986, 1993).

One of the most prominent properties of *Halorhodospira* species is their ability to adapt to the most extreme salt concentrations tolerated by eubacteria and to even grow in saturated salt solutions. They not only tolerate these high concentrations, but optimally thrive. They are extremely halophilic and *Halorhodospira halo-**phila* is the most halophilic eubacterium known (Imhoff, 1988a,b). To adapt to high and varying concentrations of salt, *Halorhodospira* species accumulate high concentrations of organic solutes to balance the outside osmotic pressure. By using ^{13}C -NMR techniques, glycine betaine has been found to be the main osmotically active cytoplasmic component in *Halorhodospira halochloris* (Galinski and Trüper, 1982). Later, a new cyclic amino acid, 1,4,5,6-tetrahydro-2-methyl-4-pyrimidinecarboxylic acid, called ectoine, and in addition trehalose were found as osmotica in *Hlr. halochloris* (Galinski et al., 1985). Ectoine appears to be widely distributed among *Halorhodospira* species and other halophilic eubacteria in general (Severin et al., 1992).

In regard to their salt responses and the salt concentrations required for optimum growth, *Ectothiorhodospira* species are slightly halophilic or marine, and some, in particular *Ect. haloalkaliphila* and *Ect. marismortui*, are moderately halotolerant. Because of its extended salt tolerance, *Ect. haloalkaliphila* may successfully compete with *Halorhodospira* species in moder-

ately saline soda lakes. To cope with the salt and osmotic stress, *Ectothiorhodospira* species (*Ect. haloalkaliphila*, *Ect. marismortui*) accumulate glycine betaine, sucrose and a third component (α -N-carbamoyl-L-glutamine amide) as osmotica (Imhoff, 1993; Imhoff and Riedel, unpubl. results; Oren et al., 1989; Severin et al., 1992). In contrast to *Halorhodospira* species, ectoine and trehalose have not been found in these species.

Ecology

The phototrophic species of Ectothiorhodospiraceae are unique purple sulfur bacteria in their requirement for saline and alkaline growth conditions. Their habitats are waters and surface layers of sediments from saline and hypersaline environments with alkaline pH, that are characterized by the predominance of processes of the sulfur cycle, so-called sulfureta. These include salt and soda lakes, but also marine sediments and stagnant coastal waters of marine environments. Many of the salt and soda lakes are enriched in nutrients and organic matter and show abundant sulfate reduction in their sediments that causes production of sulfide. The capability to perform a photoautotrophic metabolism with reduced sulfur compounds as photosynthetic electron donor makes these bacteria primary producers of biomass based on metabolic products from microbial degradation processes in the anoxic and dark parts of their environments. They thrive in the anoxic part of these habitats that receive sufficient sunlight to perform photosynthesis and quite often form massive blooms that are visible as colored waters and sediments with the naked eye (Figures 7, 8, and 9).

Applications

Like other phototrophic sulfur bacteria, *Ectothiorhodospira* species (in particular *Ect. mobilis*, *Ect. shaposhnikovii* and *Ect. vacuolata*) are suited for the removal of toxic sulfide from waste waters and principal investigations in this respect have been undertaken. Their growth requirements make possible their application under alkaline and saline conditions. The protective action of ectoine as well as glycine betaine for enzyme structure and possibly other biological structures have been analyzed and the application of these components as protective agents is discussed (e.g., Lippert and Galinski, 1992). Trehalose, ectoine and hydroxy-ectoine were the most protective against freeze-thawing and heat treatment.

Oceanospirillum and Related Genera

JOSÉ M. GONZÁLEZ AND WILLIAM B. WHITMAN

Introduction

Gram-negative, marine and/or halophilic aerobes and facultative anaerobes belong to several phylogenetic groups. Within the γ -subdivision of the Proteobacteria, a number of well known genera belonging to this group include *Alteromonas*, *Vibrio*, *Shewanella* and *Photobacterium*. This chapter covers many of the other, lesser known marine genera of the class γ -Proteobacteria, including *Alcanivorax*, *Fundibacter*, *Hahella*, *Marinobacter*, *Marinobacterium*, *Marinomonas*, *Marinospirillum*, *Microbulbifer*, *Neptunomonas*, *Oceanobacter*, *Oceanospirillum* and *Pseudospirillum*, as well as some related organisms that have not been properly classified, such as *Pseudomonas halophila* and strain 2-40. Historically, many of the species in this group have been classified with *Oceanospirillum*. Phylogenetic analyses of the 16S rRNA of these taxa suggest that, while these genera are all related, they are also fairly diverse and likely to represent a number of relatively deep phylogenetic groups (Fig. 1). Affiliated with these lesser known genera are the members of the family Halomonadaceae and the *Pseudomonas* spp. sensu stricto, both of which are discussed in other chapters. In addition, the genus *Balneatrix* is also affiliated with this group. This genus was isolated during a small outbreak of pneumonia and meningitis in humans in a spa therapy center in 1987 (Dauga et al., 1993) and grows in medium without NaCl. Although *Balneatrix* and *Pseudomonas* spp. are not primarily of marine origin, the other members of this group have only been found in marine or halophilic environments, suggesting that there is an important evolutionary distinction between freshwater and marine bacteria.

Although not a closely related group, the oceanospirilla have a monophyletic nature which is supported by several types of analyses. Except as noted below, sequence analyses of the 16S rRNA by both neighbor-joining and maximum likelihood methods support the grouping of these genera (Fig. 1). In the case of the maximum likelihood method, all branches are significantly positive ($P < 0.01$). Bootstrap analyses also indi-

cate that this clade is robust, and it appears in 95% of the replicates. Similarly, the clade containing *Shewanella*, *Vibrio*, *Alteromonas* and the Enterobacteriaceae is clearly resolved. However, this topology is altered greatly when sequences from certain symbionts of marine animals are considered. For example, addition of the sequence of a cellulolytic nitrogen-fixing organism isolated from shipworms (Distel et al., 1991) or the species “*Candidatus Endobugula sertula*,” a symbiont of the larva of the bryozoan *Bugula neritina* (Haygood and Davidson, 1997), produces deep branches within the trees and causes the sequences of the Enterobacteriaceae and related families to move inside the oceanospirilla. Because these alternative topologies are only recovered in the presence of certain sequences, they appeared to be artifacts. The monophyletic nature of these marine oceanospirilla is also supported by DNA-rRNA hybridizations in which representatives of these genera form a cluster within rRNA superfamily II (De Vos et al., 1989; Pot et al., 1989). This cluster has a $T_m(e)$ value of 68.8°C or above with members of the *Oceanospirillum* sensu stricto and also includes members of *Pseudomonas* sensu stricto and Halomonadaceae. Members of rRNA superfamily II excluded from this cluster include *Moraxella*, *Acinetobacter* and *Xanthomonas*. In addition, the Enterobacteriaceae, *Alteromonas* and related taxa were also excluded because they belonged to rRNA superfamily I.

On the basis of 16S rRNA sequence analysis, a number of phylogenetic subgroups appear to be within the oceanospirilla. *Pseudomonas* spp. sensu stricto and the family Halomonadaceae form two distinct and large clusters that are separated from each other and the oceanospirilla. *Oceanospirillum* sensu stricto also forms a closely related clade that is supported by high sequence similarities (>95.5%). Phylogenetic trees containing this clade are robust when calculated by a variety of algorithms, including parsimony and maximum likelihood, and have high bootstrap values. A group containing the genera *Marinomonas*, *Marinobacterium*, *Neptunomonas* and *Oceanobacter* is also found consistently

Fig. 1. Phylogeny of the marine taxa in the γ -subdivision of the Proteobacteria. All strains are the type strains of the species. The accession numbers for their 16S rRNA gene sequences are listed in Table 1. The accession numbers for other strains are: *Alcanivorax borkumensis*, Y12579; *Alcanivorax jadensis*, AJ001150; *Balneatrix alpica*, Y17112; *Hahella chejuensis*, AF195410; *Marinobacter aquaeoli*, AJ000726; *Marinobacter hydrocarbonoclasticus*, X67022; *Marinobacterium georgiense*, U58339; *Marinobacterium stanieri*, AB021367; *Marinomonas mediterranea*, AF063027; *Marinospirillum megaterium*, AB006770; *Microbulbifer hydrolyticus*, U58338; *Neptunomonas naphthovorans*, AF053734; *Pseudomonas elongata*, AB021368; *Pseudomonas halophila*, AB021383; and strain 2-40, AF055269. The tree was generated from the ClustalW alignment program (Thompson et al., 1994) and the neighbor-joining method using the programs in the PHYLIP package (Felsenstein, 1989). Before analysis, a filter was applied to exclude positions with less than 50% conservation within the sequences being aligned. Only positions 118 to 1396 (*Escherichia coli* numbering) were considered. *Burkholderia graminis* served as outgroup. Numbers at nodes indicate percent bootstrap values above 50 (1000 replicates). Bar indicates Jukes-Cantor evolutionary distance.

in a variety of analyses, even though the bootstrap support is modest (Fig. 1). The genus *Balneatrix* also loosely groups with these genera, although the bootstrap values are always low. Lastly, *Alcanivorax borkumensis* and *Fundibacter jadensis* are also closely related and could be classified in the same genus. In addition, the oceanospirilla contain a large number of genera that appear to represent deeply branching lineages with no close relatives in captivity:

Hahella, *Pseudospirillum*, *Marinobacter*, *Microbulbifer* and *Marinospirillum*. Presumably, as more oceanospirilla are isolated and characterized, additional representatives of these lineages will be found.

Marine bacteria have been the focus of increasing interest as a source of enzymes and biomaterials with technological applications. Many marine bacteria in this group were described because they degrade compounds of anthropogenic origin or produce polymers. Such has been the case for species of *Alcanivorax*, *Fundibacter*, *Hahella*, *Marinobacter*, *Marinobacterium*, *Marinomonas*, *Microbulbifer* and *Neptunomonas*. In addition, related but otherwise uncharacterized isolates also have demonstrated a large degradative capacity (Andrykovitch and Marx, 1988). Members of the genera *Alcanivorax*, *Fundibacter*, *Marinobacter* and *Neptunomonas* degrade components of petroleum. Some of these same organisms also produce emulsifiers that help to solubilize oil droplets. Members of these genera can be isolated from pristine environments, suggesting that they are a permanent component of marine communities (Bowman et al., 1997; Kaye and Baross, 2000; Golyshin et al., 2001). They are also inhabitants of oil reservoirs at both mesophilic and high temperatures and in environments with high concentrations of salts (Huu et al., 1999; Díaz et al., 2000; Kaye and Baross, 2000; Orphan et al., 2000; Golyshin et al., 2001). Since the formation of these genera, closely related isolates or 16S rRNA clones have been retrieved from petroleum contaminated sites (Ishihara et al., 1995; Harayama et al., 1999; Golyshin et al., 2001; Kasai et al., 2001), indicating an important role in degradation in nature. The ability to grow over a wide range of conditions, particularly in the presence of petroleum components (Geiselbrecht et al., 1996; Emerson and Breznak, 1997; Yakimov et al., 1998; Bruns and Berthe-Corti, 1999; Díaz et al., 2000; Orphan et al., 2000; Hedlund et al., 2001) or high concentrations of salts (Díaz et al., 2000; Kaye and Baross, 2000), has also been used to enrich for these bacteria. Currently the commercial potential of these bacteria is yet to be realized. A genomic sequence has not been performed for a member of this group, and no antibiotics or other secondary metabolites are commercially available.

In the last several years, an increasing number of genera have been added to the γ -3 subgroup of Proteobacteria. Other organisms with interesting characteristics have been isolated although not fully described and named. Therefore, it seems likely that many more oceanospirilla will be described in the near future. Similarly, 16S rRNA sequences of novel oceanospirilla have been retrieved directly from seawater, which suggests that these organisms are also abundant in

nature. Thus, it is likely that our understanding of this group is even more incomplete.

The Genus *Oceanospirillum*

The genus *Oceanospirillum* was originally created to distinguish the marine from the freshwater species of the genus *Spirillum*. The genus *Spirillum* has a long history and originally contained all of the known aerobic and microaerophilic spirilla, including both marine and freshwater species (Ehrenberg, 1832; Hylemon et al., 1973). As originally defined, the genus *Spirillum* possessed species containing DNA with a much broader range of mol% G+C (38–65) and more divergent phenotypic properties than is typical for modern genera. To make the genus more consistent with other taxa, Hylemon et al. (1973) and Krieg (1984) divided it into three genera. Aerobic spirilla from freshwater habitats that could not tolerate 3% NaCl and had a DNA mol% G+C of 50–65 were placed into the genus *Aquaspirillum*. Marine strains that required seawater-based medium for growth and

possessed a DNA mol% G+C of 42–48 were placed into the genus *Oceanospirillum*. The genus *Spirillum* only retained one species, *S. volutans*, which had a DNA mol% G+C of 38 and was microaerophilic.

The genus *Oceanospirillum* described by Hylemon et al. (1973) contained five species: *O. linum*, *O. minutulum*, *O. beijerinckii*, *O. maris* and *O. japonicum*. Terasaki (Terasaki, 1973; Terasaki, 1979) added four more species: *O. hirosimense*, *O. pelagicum*, *O. pusillum* and *O. multiglobuliferum*; and these nine species were described in *Bergey's Manual of Systematic Bacteriology* by Krieg (1984). In addition, at about the same time, two new species, *Oceanospirillum jannaschii* and *O. kriegii*, were described (Bowditch et al., 1984). This work also transferred two species, *Alteromonas communis* and *A. vaga* to *Oceanospirillum* (Bowditch et al., 1984).

Many of these species have since been reclassified into other genera or recognized as subjective synonyms of other species. The current taxonomic status of species that have been assigned at one time or another to *Oceanospirillum* is summarized in Table 1.

^bThe subspecies name *O. beijerinckii* subsp. *beijerinckii* (Williams and Rittenberg, 1957) Hylemon et al. (1973) was automatically created by the valid publication of *O. beijerinckii* subsp. *pelagicum* (Terasaki, 1973) Pot et al. (1989; Rule 40d [formerly Rule 46]).

^cThe subspecies name *Oceanospirillum maris* subsp. *maris* Hylemon et al. (1973) was automatically created by the valid publication of *Oceanospirillum maris* subsp. *williamsae* Linn and Krieg (1978; Rule 40d [formerly Rule 46]). The subspecies *Oceanospirillum maris* subsp. *maris* Hylemon et al. (1973), appears also in Howey et al. (1990).

Phylogeny

The phylogeny of the members of the *Oceanospirillum* core group is discussed in the introduction to this chapter.

Taxonomy

Based only upon phenotypic characteristics, members of the genus *Oceanospirillum* were heterogeneous and difficult to classify in relation to other Gram-negative bacteria (McElroy and Krieg, 1972; Terasaki, 1972; Terasaki, 1973; Hylemon et al., 1973; Carney et al., 1975; Krieg and Hylemon, 1976). The problem was compounded by the scarcity of strains in each species. Thus, other methods have contributed greatly to our current understanding of their systematics. These include DNA-DNA hybridization (Krieg, 1984),

immunological analysis (Bowditch et al., 1984; DeLong et al., 1984), DNA-rRNA hybridization (Pot et al., 1989), 16S rRNA sequence analyses (Woese et al., 1982; Satomi et al., 1998; Satomi et al., 2001), and chemotaxonomy of polyamines, fatty acids and isoprenoid quinones (Hamana et al., 1994; Sakane and Yokota, 1994). Based upon these analyses, the classification of oceanospirilla has changed considerably. These studies demonstrated that a variety of methods, in addition to phenotypic characteristics, are necessary for the proper classification of members of the *O. linum* core group.

The *Oceanospirillum* sensu stricto or the “core group” was first recognized by Pot et al. (1989), who showed by DNA-rRNA hybridization that many species previously assigned to this genus were only distantly related to the type species *O. linum*. Instead, these species appeared to rep-

resent additional genera within the rRNA superfamily II, which also included *Oceanospirillum* sensu stricto as well as the fluorescent pseudomonads, *Deleya* (now *Halomonas*), *Azotobacter*, and an assortment of other bacterial groups. These results were confirmed and extended by Satomi et al. (2001). Thus, the placement of *Altermonas vaga* and *A. communis* in a new genus *Marinomonas* and not *Oceanospirillum* was confirmed (van Landschoot and De Ley, 1983; Bowditch et al., 1984). Similarly, the need to reclassify *O. kriegii*, *O. jannaschii*, *O. japonicum*, *O. minutulum* and *O. pusillum* into new genera was recognized (Satomi et al., 2001). Although the original interpretation differed, this taxonomy was supported by the observations of Bowditch et al. (1984) and DeLong et al. (1984), who found a close immunological relationship among superoxide dismutases and glutamine synthetases from *O. linum*, *O. beijerinckii*, *M. jannaschii*, *O. kriegii*, *M. vaga* and *M. communis* to the exclusion of species of *Alteromonas*, which belonged to the rRNA superfamily I.

With regards to subspecies, the taxonomy presented here follows the recommendations of Satomi et al. (2001). In particular, we consider the subspecies *O. maris* subsp. *williamse* and *O. maris* subsp. *hiroshimense* to be reference strains of *O. maris* and not subspecies (Satomi et al., 2001). Hence, we do not use the designation "*O. maris* subsp. *maris*" for the type strain. Similarly, we also consider the subspecies *O. beijerinckii* subsp. *pelagicum* to be a reference strain and not a subspecies (Satomi et al., 2001). However, in absence of a formal ruling by the International Committee on Systematic Bacteriology (ICSB), it is important to note that the subspecies designations are still valid, and these taxa continue to possess standing in the nomenclature. The arguments for both of these treatments are as follows. The subspecies *O. maris* subsp. *williamse* was proposed to classify a strain similar to the type strain of *O. maris* discovered in a contaminated culture of *Spirillum lunatum* (Linn and Krieg, 1978). This strain (ATCC 29547) possessed many phenotypic properties in common with the type strain of *O. maris* (ATCC 27509), but their phenotypes were not identical. Subsequent investigators confirmed the close relationship between these strains and demonstrated that both strains were closely related to *O. hiroshimense* (Pot et al., 1989). On the basis of some phenotypic differences and differences in DNA hybridization and protein patterns during gel electrophoresis, each of these strains was proposed to represent a subspecies. Similarly, *O. beijerinckii* subsp. *pelagicum* was created to recognize the similarity of *O. pelagicum* to the type strain of *O. beijerinckii* (Pot et al., 1989). Although these proposals have the advantages of maintaining the epithets, they obscure the similarities between these

strains (Satomi et al., 2001). In addition, because surveys of large collections of strains have never been performed, these subspecies have not been shown to represent genetic or phenotypic groups that might exist in nature. By assigning these strains as reference strains, the taxonomy does not prejudice the question of whether subspecies exist as biological entities. The species remaining in the *Oceanospirillum* core group are phenotypically and genotypically similar (Tables 2 and 3). They are Gram-negative spirilla, which are motile by bipolar flagellar tufts. They are heterotrophs and obligate aerobes whose major substrates are amino acids or organic acids but not sugars. They possess a DNA mol% G+C of 45–50. Spermidine is the most abundant polyamine, and the most abundant nonpolar fatty acids are C16 : 1, C16 : 0, and C18 : 1.

Habitat

Most research on the distribution of *Oceanospirillum* spp. was performed prior to the development of molecular methods and the reorganization of its taxonomy. Therefore, it is not clear whether the earlier descriptions of morphotypes in natural environments refer to the core taxon of *Oceanospirillum* or other, morphologically similar but phylogenetically different groups (Pot et al., 1992). So far, rRNA genes closely related to *Oceanospirillum* species have not been encountered in libraries prepared from marine environmental rDNA (Giovannoni et al., 2000), which suggests that the abundance of *Oceanospirillum* in the marine environment is low. On the other hand, strains whose 16S rDNA possessed 93–95% sequence similarity to *Oceanospirillum* sensu stricto were isolated relatively frequently from seawater without prior enrichment on a low nutrient, complex medium, marine R2A agar (Suzuki et al., 1997). Therefore, the members of this taxon cannot be too rare.

What is known about the distribution of the spirillum morphotype in marine samples has been reviewed by Pot et al. (1992). Marine spirilla have been isolated from the alimentary tracts of shellfish, seawater samples taken from the intertidal zone, and decaying seaweed. The abundance in the open sea is unknown, although direct observation of low numbers of spirilla in the Gulf of Mexico has been reported (Oppenheimer and Jannasch, 1962).

Isolation

The species of *Oceanospirillum* in the core group have been isolated from enrichments of coastal seawater and infusions of marine shellfish (Williams and Rittenberg, 1957; Hylemon et al., 1973; Terasaki, 1970; Terasaki, 1973; Terasaki, 1979). Suzuki et al. (1997) isolated organisms that were

Data from Pot et al. (1992) and also Terasaki (1972).

related to the *Oceanospirillum* core group without enrichment using a modified version of R2A medium (Reasoner and Geldreich, 1985). This medium contained in g/liter of 75% seawater: yeast extract, 0.5; proteose peptone, 0.5; casamino acids, 0.5; dextrose, 0.5; soluble starch, 0.5; sodium pyruvate, 0.3; and agar, 15. The plates were inoculated directly with 100 μ l of seawater and incubated at 15°C in the dark.

Most marine spirilla have been isolated by enrichment since they seldom predominate in the original samples. Isolation procedures included dilution in rich medium and growth in putrid infusions.

ISOLATION BY DILUTION Williams and Rittenberg (1957) isolated strains of *O. linum* and *O. beijerinckii* from enrichments of coastal seawater followed by a dilution technique (Krieg, 1984). Seawater was mixed with an equal volume of Giesberger's medium containing (per liter): 1 g of NH_4Cl , 0.5 g of K_2HPO_4 , 0.5 g of $\text{MgSO}_4 \cdot 7 \text{H}_2\text{O}$, with 1% calcium lactate (Giesberger, 1936). After incubation and once spirilla appeared, a portion of the culture was autoclaved. It was then mixed with an equal volume of Giesberger's medium that lacked NH_4Cl . This medium was then inoculated with the unsterilized portion of the initial culture. Spirilla predominated after one to three subcultures in this medium. For isolation, the enrichment was diluted 1 : 100 to 1 : 100,000 in sterile seawater. After mixing, the flasks were allowed to stand for 20 minutes to allow the spirilla to migrate to the surface. Plates with the appropriate medium were then inoculated with surface water.

ISOLATION FROM PUTRID INFUSIONS Marine mussels and other shellfish such as *Ruditapes philippinarum*, *Crassostrea gigas*, *Batillaria multiformis* and *Mytilus edulis* were the source of strains of *O. multiglobuliferum*, *O. beijerinckii* and *O. maris* (Terasaki, 1973; Terasaki, 1979). In a typical enrichment, the bodies of one to three shellfish smashed with a hammer were submerged in a Petri dish containing 2.5% NaCl. The suspension was incubated for up to 3 days at 20–30°C. Spirilla frequently became apparent by microscopic examination early in the putrefaction. As soon as spirilla were abundant, a loopful of the suspension was removed, and the loop was touched successively to a glass slide to produce small droplets. The smallest of these droplets was then streaked on to agar medium containing peptone and 2.75% NaCl.

Preservation

Oceanospirilla grow in media containing natural or synthetic seawater (Williams and Rittenberg, 1957; Hylemon et al., 1973), and isolates may be

maintained in semisolid PSS medium at 30°C with weekly transfer (Hylemon et al., 1973) or as stab at room temperature in seawater nutrient agar with monthly transfer (Terasaki, 1972).

Peptone-Succinate-Salt (PSS) Medium

Peptone	10 g
Succinic acid	1 g
$(\text{NH}_4)_2\text{SO}_4$	1 g
$\text{MgSO}_4 \cdot 7 \text{H}_2\text{O}$	1 g
$\text{FeCl}_3 \cdot 6 \text{H}_2\text{O}$	0.002 g
$\text{MnSO}_4 \cdot \text{H}_2\text{O}$	0.002 g
Agar	1.5 g
Synthetic seawater	1 liter

The pH is adjusted to 7.8.

Synthetic Seawater

NaCl	27.5 g
MgCl_2	5 g
$\text{MgSO}_4 \cdot 7 \text{H}_2\text{O}$	2 g
CaCl_2	0.5 g
KCl	1 g
FeSO_4	0.01 g
Distilled water	1000 ml

Preservation can be accomplished by suspending a dense suspension of cells in seawater nutrient broth containing 10% (v/v) dimethyl sulfoxide, with subsequent freezing in liquid nitrogen (Krieg, 1984). Freeze-drying can be performed with cells grown on the appropriate medium (Terasaki, 1975).

Identification

The properties of the species of *Oceanospirillum* sensu stricto are summarized in Tables 2 and 3 and below. The description of *Oceanospirillum linum* is based upon the description of *Spirillum linum* and *S. atlanticum* by Williams and Rittenberg (1957), Terasaki (1972) and Hylemon et al. (1973). The description of *Oceanospirillum maris* is based upon the description of strains 35, 36 and 37 of Hylemon et al. (1973) and *Spirillum hiroshimense* OF2 and AF1 of Terasaki (Terasaki, 1972; Terasaki, 1979). The description of *Oceanospirillum beijerinckii* is based upon the description of Hylemon et al. (1973) and *Spirillum pelagicum* UF1, AF2 and IF5 of Terasaki (Terasaki, 1972; Terasaki, 1979). The description of *Oceanospirillum multiglobuliferum* is based upon the description of Terasaki (Terasaki, 1972; Terasaki, 1979). Cells are spirilla, 0.2–1.2 μ m in diameter and 2–40 μ m in length. They form a clockwise helix, with a helical diameter of 0.7–2.8 μ m and a wavelength of 1.57 μ m. At the cell poles, a “polar membrane” underlies the cytoplasmic membrane in all species examined so far by electron microscopy. Cells also possess a Gram-negative envelope and bipolar tufts of flagella.

Cells are chemoorganotrophs and strict aerobes. Nitrate is not reduced to nitrite. Denitrifi-

cation has not been observed. Sugars are neither oxidized nor fermented. As noted in Table 3, organic acids serve as sole carbon sources for most species. Of the common amino acids, only the few shown in Table 3 are utilized. For *O. linum* and *O. beijerinckii*, amino acids, urea, nitrate, and nitrite will not serve as sole nitrogen sources. Some strains of *O. maris* utilize many but not all of the common amino acids as well as urea. *Oceanospirillum multiglobuliferum* utilizes asparagine and urea weakly, but the other amino acids have not been tested. Casein, starch, hippurate or esculin are not hydrolyzed. Growth factors are required for *O. linum* but not the other species. Cells accumulate granules of poly- β -hydroxybutyrate (PHB). Cells are oxidase positive and indole negative.

In older cultures after 3–4 weeks, coccoid cells predominate for all species in the *Oceanospirillum* core group. In the case of *O. multiglobuliferum*, these coccoid bodies predominate after only 1–2 days. Coccoid cells are also found in older cultures of some spirilla no longer classified in the core group: *Marinospirillum minutulum* and *Terasakella pusillum*. However, *Marinobacterium jannaschii* and *Pseudospirillum japonicum* do not form these bodies. These coccoid bodies germinate in fresh medium, reforming cells with the spirillum morphology (Krieg, 1984).

Cells require seawater for growth. The range of NaCl for growth is 0.5–8.0% in medium with peptone (Terasaki, 1972; Terasaki, 1979), although they can also grow with 9.75% NaCl but not with 12.75% in PSS medium (Hylemon et al., 1973). The optimum growth temperature is 25–35°C.

The mol% G+C of the DNA ranges from 45 to 50. The type species is *Oceanospirillum linum* (Williams and Rittenberg, 1957) Hylemon, Wells, Krieg and Jannasch 1973^{AL}. The type strain is *O. linum* ATCC 11336.

For the identification of new species, other techniques such as rRNA sequencing and DNA–DNA hybridization are recommended to supplement the phenotypic identification.

The Genus *Marinospirillum*

The genus *Marinospirillum* was created to accommodate *Oceanospirillum minutulum*, which was originally classified as *Spirillum minutulum*, and a new isolate *Marinospirillum megaterium* (Watanabe, 1959; Satomi et al., 1998). When the genus *Spirillum* was divided into the fresh water and marine species, *M. minutulum* was moved to *Oceanospirillum* along with the other marine forms. However, a number of methods indicated that this species was only distantly related to the *Oceanospirillum* core

group. It possessed only low phenetic similarity to the type species *Oceanospirillum linum* (Terasaki, 1972; Carney et al., 1975). DNA–rRNA hybridizations also indicated that *O. linum* was no more closely related to *M. minutulum* than species from other genera in RNA superfamily II (Pot et al., 1989). Similarly, the fatty acid composition of *M. minutulum* was significantly different from that of members of the *Oceanospirillum* sensu stricto (Sakane and Yokota, 1994). Finally, it was classified on the basis of the 16S rRNA gene sequence as the type species of a new genus, *Marinospirillum*, along with the new isolate *M. megaterium* (Satomi et al., 1998).

Both species of *Marinospirillum* were isolated from environments rich in organic matter. *Marinospirillum minutulum* was isolated from a putrid infusion of a marine shellfish (Watanabe, 1959). Enrichment was carried out in synthetic medium with peptone, and the bacterium was finally isolated in medium with calcium lactate and peptone as carbon sources. Two strains of *M. megaterium* were isolated from kusaya gravy, used to make Japanese dried fish (Satomi et al., 1998). This gravy is rich in nutrients, contains 3% NaCl, volatile nitrogen compounds, and low oxygen concentrations. The strains were enriched on the basis of their high motility, which allowed them to migrate rapidly through medium in a horizontal glass tube. Following repeated enrichment in this manner, pure cultures were isolated upon streaking on Petri plates. Apparently, the ability to form colonies on Petri plates is low, and this property was lost upon subsequent transfers.

The phenotypic properties of the species of *Marinospirillum* are described in Tables 2 and 4. In addition, the spirillum of *M. minutulum* forms a clockwise spiral with a helical length of 1.5–3.0 μm and a helical diameter of 0.8–1.3 μm (Terasaki, 1972; Fig. 2). *Marinospirillum minutulum* could not grow with the following sole carbon sources: arabinose, galactose, lactose, maltose, mannose, saccharose, *n*-butanol, ethylene glycol, and mannite (Terasaki, 1972). Hylemon et al. (1973) further reported that this species was able to grow with 2-ketoglutarate, glutamate, glutamine and proline but not with aconitate, isocitrate, caproate, 2-hydroxybutyrate, hydroxyproline, ornithine, citrulline, putrescine, or any of the remaining common amino acids (except for tryptophan and threonine, which were not tested). As sole nitrogen sources, it utilized ammonia, asparagine and urea, but not nitrite and nitrate (Terasaki, 1972). In addition, Hylemon et al. (1973) found that it utilized alanine, aspartate, glutamine, asparagine, proline, histidine, leucine, and valine as sole nitrogen sources, but not the other amino acids tested. The major nonpolar fatty acids of *M. minutulum* are C16:0 (35%), C18:1 (32%),

^aBy the HPLC method.

^bBy the thermal denaturation method.

The data is from Watanabe (1959), Terasaki (1972), Hylemon et al. (1973), Carney et al. (1975), Sakane and Yokota (1994) and Satomi et al. (1998). For the pH, temperature, and NaCl ranges, the description of *M. minutulum* by Terasaki (1972) and Satomi et al. (1998) differed slightly. The values reported are those of the latter authors.

and C16:1 (26%; Sakane and Yokota, 1994). The major 3-hydroxy fatty acids are C12:0 (61%) and C14:1 (36%). The most abundant polyamines are spermidine (0.72 µmol/g of wet cells) and

putrescine (0.10 µmol/g of wet cells; Hamana et al., 1994).

On the basis of phenotypic tests, both Terasaki (1972) and Hylemon et al. (1973) concluded that

Fig. 2. Scanning electron micrographs of *Marinospirillum megaterium* H7 as vegetative cells (a), coccoid bodies (b), and negatively stained in (c). Bar is 1 μ m (a, b) and 2 μ m (c). Reproduced with permission (T. Fujii, Tokyo University of Fisheries, Japan).

strain ATCC 19192 was nearly identical to the type strain of *M. minutulum* ATCC 19193. ATCC 19192 was originally deposited as *Spirillum halophilum* (Watanabe, 1959), but the properties of the ATCC culture differed from those of the original description. For that reason, Hylemon et al. (1973) proposed that both strains be considered members of *M. minutulum*.

Marinospirillum shares with *Oceanospirillum* a number of characteristics. Both are Gram negative, halophilic, possess a helical shape, form coccoid bodies, and lack the ability to catabolize carbohydrates. The DNA mol% G+C content of *Marinospirillum* is slightly outside the range of the oceanospirilla (42–45 vs 45–50 for *Oceanospirillum*). Moreover, these two genera share a low level of DNA hybridization, and the sequence similarities of their 16S rRNA and *gyrB* genes are low (Pot et al., 1989; Satomi et al., 1998; Satomi et al., 2001). Phylogenetic analyses suggest that *Marinospirillum* may be phylogenetically more closely related to the Halomonadaceae than to *Oceanospirillum sensu stricto* (Fig. 1).

The Genus *Pseudospirillum*

Watanabe (1959) isolated the type strain (ATCC 19191 or IFO15446) from putrid infusions of shellfish and described it as *Spirillum japonicum*. As with other marine spirilla, this species was enriched in seawater-based medium containing peptone as carbon source, and it was isolated in calcium lactate and peptone medium. Terasaki (Terasaki, 1963; Terasaki, 1972) described three similar strains that may belong to this or a closely related species, IF4 (IFO 15447), IF8, and UF3. These strains were all isolated from putrid infusions of shellfish at 25–30°C. The shellfish were crushed with a hammer and suspended in a 2.5% solution of NaCl in a sterile Petri plate. Microscopic observation indicated that spirilla became abundant just as the solution turned turbid. At this time, usually after 1–3 days, a small droplet was streaked onto peptone-marine salts plates for isolation.

The original classification of *S. japonicum* was based on cellular morphology. Hylemon et al. (1973) reclassified it along with the other marine strains of *Spirillum* into a new genus, *Oceanospirillum*. However, a number of independent lines of investigation indicated that this species was only distantly related to the *Oceanospirillum* core group. It possessed only low phenetic similarity to the type species *Oceanospirillum linum* (Terasaki, 1972; Carney et al., 1975). DNA-rRNA hybridizations indicated that *O. linum* was no more closely related to *P. japonicum* than species from other genera in RNA superfamily II (Pot et al., 1989). Similarly, the fatty acid composition of *P. japonicum* was significantly different from that of members of the *Oceanospirillum sensu stricto* (Sakane and Yokota, 1994). Finally, on the basis of the 16S rRNA gene sequence, it was classified as the type species of a new genus, *Pseudospirillum* (Satomi et al., 2001).

The characteristics of *P. japonicum* are described below and in Table 2. Cells of *P. japonicum* have a diameter of 0.8–1.4 μm and length of 4–15 μm . Terasaki (1972) failed to observe the helical form in the type strain, although a clockwise spiral was observed in other, closely related strains. Cells appeared as curved, straight, or flattened S-shaped rods. Longer cells, up to 75 μm in length, observed by both Watanabe (1959) and Hylemon et al. (1973), formed gentle spirals with a wavelength and helical diameter of 8–20 μm and 2–5 μm , respectively. Cells are slowly motile by means of bipolar flagellar tufts. Unlike many oceanospirilla, older cultures do not form cocci or microcysts.

Pseudospirillum japonicum grows under aerobic and microaerobic conditions (Terasaki, 1972). It does not respire nitrate, and it does not utilize sugars and most amino acids as sole carbon sources (Terasaki, 1972; Hylemon et al., 1973). In addition to the compounds listed in Table 3, compounds utilized include propionate, butyrate, fumarate, oxaloacetate, lactate, malate, alanine, glutamate and glutamine. None of the other common amino acids tested were utilized as sole carbon sources. Other compounds not utilized included the alcohols tested (methanol and ethanol), citrate, isocitrate and formate. In contrast, most of the common amino acids were utilized as nitrogen sources (Hylemon et al., 1973), and urea supported poor growth (Terasaki, 1972). Nitrite and nitrate were not utilized as sole nitrogen sources, and they were not reduced.

Pseudospirillum japonicum grows well in marine medium with 0.5–8 % NaCl (Terasaki, 1972). Growth was also obtained at initial pH values of 6.0–9.0. Higher values were not tested, and no growth was observed at pH 5.5. The temperature optimum for growth is about 35°C, and the temperature range is 11–42°C, with no growth observed at 9 and 44°C (Terasaki, 1972).

In biochemical tests, *P. japonicum* produces phosphatase, reduces selenite, and grows with 1% bile salts (Hylemon et al., 1973). It is negative for the following tests: hydrogen sulfide and indole production, casein and hippurate hydrolysis, esculin, DNase, RNase, methyl red and Voges-Proskauer, and growth with 1% glycine, triple sugar iron (TSI) agar, eosin-methylene blue (EMB) agar, and MacConkey agar.

The nonpolar major fatty acids of *P. japonicum* are C16:1 (55%), C16:0 (24%), and C18:1 (18%; Sakane and Yokota, 1994). The major 3-hydroxy fatty acid is C12:0 (97%). In addition, the most abundant ubiquinone is Q-8 (86%). The polyamines are spermidine, 1.17 $\mu\text{mol/g}$ of wet weight, and putrescine, 0.01 $\mu\text{mol/g}$ of wet weight (Hamana et al., 1994). The mol% G+C of the

DNA is 44.5% by liquid chromatography and 45–46% by thermal denaturation (Hylemon et al., 1973; Carney et al., 1975; Sakane and Yokota, 1994).

The sequence of the 16S rRNA gene of this species does not cluster with any other marine γ -Proteobacteria, and the percent similarities with described genera are all below 90%. The following characteristics define the genus: Gram-negative, curved, straight or S-shaped cells, nonsporeforming, halophilic, aerobic, chemoheterotrophic, and PHB-accumulating. Organisms do not form coccoid bodies, are motile by means of bipolar flagellar tufts, and are oxidase positive. Carbohydrates are not catabolized. The mol% G+C content of the DNA is 44–46%. The ubiquinone type is Q-8. The type species is *Pseudospirillum japonicum*. The type strain is ATCC 19191 (IFO 15446).

The Genera *Alcanivorax* and *Fundibacter*

The members of this genus were originally described because they grow on oil-derived compounds, although they have also been isolated from pristine environments. The type species in the genus, *Alcanivorax borkumensis*, was isolated from an enrichment culture with a mixture of *n*-alkanes as the sole carbon source in seawater-based medium (Yakimov et al., 1998). The strains within this species are aerobic, Gram-negative, nonsporeforming, catalase and oxidase positive, and nonmotile rods. They catabolize a restricted spectrum of carbon sources and produce surfactants for the degradation of *n*-alkanes.

A species closely related to *Alcanivorax*, *Fundibacter jadensis*, was isolated by enrichment with hexadecane (Bruns and Berthe-Corti, 1999). Its growth requirements are very similar to those of *Alcanivorax* (Table 5) and the sequence similarity of their 16S rRNA genes is 98%. In contrast, measurements of the DNA mol% G+C contents of these two genera are far apart (53.4 and 63.6 for *A. borkumensis* and *F. jadensis*, respectively), although the differences in methods might explain the different contents. Golyshin et al. (2001) recently unified *Alcanivorax* and *Fundibacter* into one genus. Because *Alcanivorax* was the first genus described, it had priority. Thus, *Fundibacter jadensis* became *Alcanivorax jadensis*.

Alcanivorax strains can be isolated from seawater or marine sediments already contaminated with oil or by enrichment with hydrocarbons, either as a mixture or with a single compound (such as *n*-hexadecane). Strain MBIC 4326 was

isolated by enrichment from seawater and is able to grow on *n*-alkylcycloalkanes and *n*-alkylbenzenes (Dutta and Harayama, 2001). Harayama et al. (1999) enriched *Alcanivorax* by adding inorganic nutrients (per liter: NH₄NO₃, 1 g; K₂HPO₄, 0.2 g; and ferric citrate, 20 mg) and crude oil to pristine seawater samples. After one week of incubation at 20°C, up to 90% of the bacterial cells were estimated to be *Alcanivorax* using fluorescent in situ hybridization (FISH). Different methods have been used to detect

Alcanivorax spp. in seawater without cultivation. Kasai et al. (2001) detected *Alcanivorax* in both water samples and oil paste at the site of an accidental oil spill using denaturing gradient gel electrophoresis (DGGE). Members of the genus were also detected without cultivation from different marine environments (Ishihara et al., 1995; Harayama et al., 1999; Golyshin et al., 2001; Kasai et al., 2001).

The two species of *Alcanivorax* are Gram-negative rods, 0.3–0.7 µm wide and 0.8–3 µm long

(Figs. 3 and 4). In medium with alkanes as the sole carbon source, the size is larger. They are capable of anaerobic growth with nitrate and are catalase and oxidase positive. Carbon sources are limited to acetate and a few other simple organic compounds as well as aliphatic and aromatic hydrocarbons. Members of the genus are

Fig. 3. Negatively stained *Alcanivorax jadensis* T9 cells in medium with 2 ml of hexadecane per liter of modified nutrient broth. Pili are visible. Reproduced with permission (L. Berthe-Corti, University of Oldenburg, Germany).

moderately halophilic, the optimal NaCl for growth is 3–10%, and the optimum temperature is 20–30°C. Some members produce surfactants. Abundant fatty acids in the phospholipids include C16:0; sum of C16:1&969;7*cis* and C16:1&969;9*trans*; the sum of C18:1&969;7*cis*, C18:1&969;7 *trans*, C18:1&969;9*trans*, and C18:1&969;12 (these were not resolved by the chromatography system used); and an unidentified fatty acid. Colonies grown on alkane media are circular and transparent, turning opaque and light yellow following days of incubation. The type species is *Alcanivorax borkumensis* strain SK2 (DSM 11573). Phenotypically, the two *Alcanivorax* species are similar to *Marinobacter* spp., which also tolerate high concentrations of salts, do not grow on carbohydrates, and degrade hydrocarbons.

The Genus *Hahella*

The description of this genus is based on a single strain, 96CJ10356, that produces large amounts of an emulsifying agent composed of exopolysaccharides (Lee et al., 2001). *Hahella* was isolated from marine sediments on a rich medium containing 5 g of peptone, 1 g of yeast extract, 0.01 g of FePO₄ in 75% aged seawater. Colonies are red pigmented.

Fig. 4. Ultrathin sections of *Alcanivorax borkumensis* at different growth conditions. (a) Cells of *A. borkumensis* are growing at the water-alkane interface. Many cells show irregular morphology under these growth conditions. Characteristically electron translucent inclusions, which often dictate the outer cell shape, can be seen in cells with this physiological state. Additionally, alkane-grown cells (b) have a larger cell volume and produce more inclusions (asterisks) than (c) their pyruvate-grown counterparts. These inclusions often appear associated with the nucleoplasm (white arrowheads). Reproduced with permission (P. N. Golyshin and H. Lünsdorf, German Research Centre for Biotechnology, Braunschweig, Germany).

Fig. 5. Scanning electron micrographs of *Hahella chejuensis* in young (1-day) cultures (a). The cells become shorter in old (7-day) cultures (b). Reproduced with permission (K. S. Bae, Research Institute of Bioscience and Biotechnology, Taejon, Republic of Korea).

The following characteristics define the genus *Hahella*: the cells are Gram-negative rods each with a single polar flagellum (Fig. 5). This facultative aerobe reduces nitrate to nitrite, is oxidase and catalase positive, grows on carbohydrates with the production of acids, and hydrolyzes esculin and gelatin (Table 2). The mol% G+C of the DNA is 55 (thermal denaturation method). The type and only species is *Hahella chejuensis* strain 96CJ10356 (Korean Collection for Type Cultures number 2396). The phylogenetic classification is also unclear since only one 16S rRNA sequence exists. The percent similarity with any other sequence of the rRNA superfamily II is below 90%. Thus, *Hahella* represents a deep branch of this group.

The Genus *Marinobacter*

The genus *Marinobacter* only contains two species, *M. hydrocarbonoclasticus* and *M. aquaeoli*. This genus is of increasing interest because many marine isolates have been characterized whose 16S rRNA sequences indicate that they could be classified in this genus. These isolates come from a variety of sources, including both pristine (Baumann et al., 1972; Pinhassi et al., 1997; Eilers et al., 2000; Hagström et al., 2000) as well as oil-contaminated environments (Gauthier et al., 1992; Emerson and Breznak, 1997; Rontani et al., 1997; Button et al., 1998; Díaz et al., 2000; Hedlund et al., 2001), hydrothermal vents (Takami et al., 1999; Kaye and Baross, 2000), sea ice (Gosink and Staley, 1995; Bowman et al., 1997), sulfide-rich sediments (Tanner et al., 2000) and oil reservoirs (Huu et al., 1999; Orphan et al., 2000). Thus, new species are likely to be described in the future that will extend the diversity of this genus.

Marinobacter hydrocarbonoclasticus, the first species described in this genus, was named for its ability to grow on hydrocarbons. Other strains have since been isolated from oil-contaminated environments and oil reservoirs. *Marinobacter*

aquaeoli was isolated from an oil-producing well (Huu et al., 1999) and was also able to grow on *n*-hexadecane, pristane and other oil components. Strains of *Marinobacter* have been also isolated from nonpolluted environments. Baumann et al. (Baumann et al., 1972; Baumann et al., 1983) described 34 strains of aerobic, oxidase-positive, Gram-negative, motile marine bacteria from pristine environments and classified them as *Pseudomonas nautica*. On the basis of its 16S rRNA gene sequence and DNA-DNA hybridization, *P. nautica* was reclassified as another strain of *M. hydrocarbonoclasticus* (Kita-Tsukamoto et al., 1993; Spröer et al., 1998).

Phylogeny

The 16S rRNA sequences of *M. hydrocarbonoclasticus* and *M. aquaeoli* are 95.7% similar. *Marinobacter* sp. strain CAB, which was isolated for its ability to degrade isoprenoid compounds from hydrocarbon-polluted sediments with nitrate as electron acceptor (Rontani et al., 1997), was proven later to be a strain of *M. hydrocarbonoclasticus* on the basis of its 16S rRNA sequence and DNA-DNA hybridization data (Spröer et al., 1998). The 16S rRNA of the type strain of *M. hydrocarbonoclasticus*, strain CAB, and strain DSM 50418 (formerly the type strain of *Pseudomonas nautica*) possess nearly 100% sequence similarity (Spröer et al., 1998).

Taxonomy

The characteristics of the two species in the genus *Marinobacter* are shown on Tables 2 and 6. In addition, information on the type strain of *P. nautica* was included in the description of *M. hydrocarbonoclasticus* (Baumann et al., 1972; Baumann et al., 1983). Information on the other strains was not included because, in the absence of rRNA sequences, their affiliation with this taxon is still uncertain.

Stan-Lotter, Institut für Genetik und Allgemeine Biologie, Salzburg, Austria; G. Wanner, Botanisches Institut der Universität München, München, Germany).

Identification

The characteristics of the genus are as follows: Gram negative, rod-shaped, nonsporeforming, 0.3–0.6 μm by 1.4–3.0 μm , motile by means of a single polar flagellum (Fig. 6). Optimal growth is at 30–32°C, and the temperature range is 10–50°C. The optimal NaCl concentration for growth is 3–6%, but growth is observed in up to 20% NaCl. Growth is aerobic, nonfermentative, or anaerobic with nitrate or nitrite. Cells are oxidase and catalase positive. They utilize a few amino acids for growth but not carbohydrates. Acetate, butyrate, succinate, lactate, fumarate and citrate are also utilized as well as a range of aliphatic and aromatic compounds. Strains have been isolated from the marine habitat, especially from oil-contaminated environments. The mol% G+C of the DNA is 56–58 (HPLC method). The type species is *Marinobacter hydrocarbonoclasticus* strain ATCC 49840.

Physiology

Members of this genus are known for their ability to degrade compounds present in oil. Fernandez-Linares et al. (1996) studied the effect of NaCl concentrations on the degradation of eicosane by the type strain of *M. hydrocarbonoclasticus*. Under different conditions, the rate of degradation of this compound did not change, and an emulsifying agent was produced for the attachment of the cells to the hydrocarbon and further degradation.

Marinobacter hydrocarbonoclasticus possesses vesicles or blebs made out of the outer membrane that are associated with the cells or free in the culture medium (Fernandez-Linares

et al., 1996; Gauthier et al., 1992). These vesicles may function in the uptake of nutrients from the surroundings, inasmuch as they increase the surface area of the cell. They could also be involved in the degradation of insoluble compounds. These vesicles are mostly produced when the carbon source in the medium is an insoluble compound such as eicosane. Similar vesicles have been seen in Gram-negative and Gram-positive bacteria, and in some cases, activities of hydrolytic enzymes have been found associated with the vesicles (Forsberg et al., 1981; Antrankian et al., 1987; Gauthier et al., 1992; González et al., 1997). Unidentified bacteria inside decaying wood also produce these vesicles (Daniel et al., 1987; Singh et al., 1990).

Rontani et al. (1999) describe the production of isoprenoid wax esters by all three strains of *M. hydrocarbonoclasticus* during growth on the isoprenoid compounds 6, 10, 14-trimethylpentadecan-2-one and phytol. The formation of wax esters from these types of compounds had not been previously described in bacteria and may provide an explanation for the existence of wax esters in marine or lacustrine sediments. However, the distribution of this activity in other marine bacteria is not known, so the importance of *Marinobacter* in this process remains to be demonstrated.

Isolation

Baumann et al. (1972) enriched for *P. nautica* (*M. hydrocarbonoclasticus*) on the basis of its ability to denitrify in medium containing 0.2% sodium butyrate (Baumann et al., 1971). Presumably, strains of this genus could also be enriched in medium with the components of oil. Kaye and Baross (2000) selected for *Marinobacter* and *Halomonas* strains. Using broth containing 16% NaCl and a carbon source of 0.1% sodium citrate, they were able to grow 0.01–28% of the bacteria in various samples of seawater. Partial sequences of the 16S rRNA gene from 14 isolates indicated that they belonged to either *Marinobacter* or *Halomonas*. Thus, similar growth conditions could be used for the isolation of new *Marinobacter* strains.

Marinobacter strains also produce an emulsifying agent that allows them to attach to hydrocarbon particles (Fernandez-Linares et al., 1996). This characteristic might be useful for the isolation of additional species.

The Genus *Marinobacterium*

The type species *Marinobacterium georgiense* was isolated from coastal seawater by enrichment and dilution in medium that contained filter-

sterilized seawater and low amounts of reduced nitrogen and phosphate. The carbon source was the high molecular weight fraction of pulp mill effluent, which contained mainly lignin and lower amounts of cellulose and hemicellulose (González et al., 1997). The genus also contains strains formerly classified in the genera *Oceanospirillum* and *Pseudomonas*. Satomi et al. (2001) proposed that *Oceanospirillum jannaschii* (Bowditch et al., 1984) and *Pseudomonas stanieri* (Baumann et al., 1983) represent species of *Marinobacterium*. In addition, on the basis of high DNA-DNA hybridization to *M. georgiense*, *Pseudomonas iners* (Iizuka and Komagata, 1964) was reclassified as a reference strain of this species (Satomi et al., 2001). These assignments were supported by analyses of both the 16S rRNA and *gyrB* gene sequences, as well as phenotypic characteristics and mol% G+C content of the DNA. For instance, the 3-hydroxy fatty acid profile of *P. iners* is different from that of *Pseudomonas aeruginosa* and related taxa (Oyaizu and Komagata, 1983), which supports its classification in another genus. On the basis of DNA-rRNA

hybridization data, Pot et al. (1989) also suggested that *Oceanospirillum jannaschii* had been misclassified and that this species should be included in a separate genus. Moreover, the original criteria used to classify *M. jannaschii* in the genus *Oceanospirillum* were very general and included a requirement of seawater for growth, accumulation of poly- β -hydroxybutyrate, inability to utilize carbohydrates and a mol% G+C of the DNA within the range of 42–52%. Many organisms that are only distantly related are now known to share these characteristics.

The characteristics of the genus are as follows: Cells are rod-shaped, Gram negative, and motile by means of a single polar flagellum (Tables 2 and 7; Fig. 7). They are strict aerobes, able to grow on a wide range of substrates, including carbohydrates, organic acids, amino acids and aromatic compounds. Nitrate may be reduced. They are oxidase and catalase positive. Gelatin is not liquified. Poly- β -hydroxybutyrate is accumulated. The mol% G+C of the DNA is 55. The type species is *Marinobacterium georgiense* strain KW-40 (ATCC 700074).

Marinobacterium spp. may be involved in the transformation of important sulfur compounds. Dimethylsulfoniopropionate (DMSP) is an osmolyte of marine algae and an important S-containing compound in seawater, especially in coastal environments. Dimethylsulfide (DMS) is derived from DMSP and is also an important intermediate in the global sulfur cycle. Because it is volatile, DMS plays a role in the transportation of sulfur to the atmosphere and cloud formation (Charlson et al., 1987). Ansedé et al. (2001) used a medium containing 1 mM DMSP to isolate strains of *Marinobacterium* spp. Another strain, DMS-S1, was isolated on succinate and was able to use DMS as sulfur source only in the presence of light (Fuse et al., 2000). Compounds like DMS and other organic sulfur

compounds are also produced during wastewater treatment and are of environmental concern. *Marinobacterium georgiense* was isolated from enrichment with pulp mill effluent, which also contains high molecular weight organic sulfur and aromatic compounds.

Marinobacterium 16S rRNA sequences were obtained from water samples associated with an oil reservoir after amplification with universal primers (Voordouw et al., 1996). Out of a total of 47 sequences analyzed, 12 belonged to the *Marinobacterium* group, which indicated that this genus was abundant in these samples and may be involved in the oxidation of sulfide that originated from sulfate reduction. The salinities in the samples ranged from 2–7% NaCl.

The Genus *Marinomonas*

Many of the aerobic, Gram-negative heterotrophs isolated from seawater are members of the genera *Alteromonas* or *Marinomonas*. Because these genera share many phenotypic characteristics, they were discussed in the same chapter of the 2nd edition of *The Prokaryotes*. *Marinomonas* contains three species, *M. communis*, *M. vaga* and *M. mediterranea*.

The species *M. communis* and *M. vaga* were originally described as species of *Alteromonas* (Baumann et al., 1972). The genus *Alteromonas* was created to accommodate Gram-negative heterotrophs with a single polar flagellum that differed from *Pseudomonas* on the basis of their low DNA mol% G+C (38–50). In contrast, the

DNA mol% G+C of *Pseudomonas* ranged from 55 to 64 (Baumann et al., 1972). *Alteromonas communis* and *Alteromonas vaga* could be distinguished from other *Alteromonas* spp. by their ability to utilize D-sorbitol, DL-malate, α -ketoglutarate and *m*- and *p*-hydroxybenzoate, and their inability to produce gelatinase or lipase (Baumann et al., 1984). In addition, they degrade aromatic compounds, whereas *Alteromonas* spp. do not (Baumann et al., 1972). They also possess bipolar flagella, as opposed to *Alteromonas* spp., which have only one polar flagellum (Baumann et al., 1984). Lastly, van Landschoot and De Ley (1983) demonstrated that *A. vaga* and *A. communis* belonged to a different DNA-rRNA hybridization group than other species of *Alteromonas* and created the genus *Marinomonas*. The type species is *M. communis*, and the type strain is *M. communis* ATCC 27118. Only a year later, Bowditch et al. (1984) independently proposed that these species be classified within *Oceanospirillum*, on the basis of immunological studies of the iron-containing superoxidase dismutases and glutamine synthetases. They found that these enzymes crossreacted most strongly with antisera prepared to the enzymes from *Oceanospirillum beijerinckii* and *Oceanospirillum jannaschii*. They also further characterized species in the genus *Oceanospirillum*, as well as 33 and 17 strains of *M. communis* and *M. vaga*, respectively. However, Pot et al. (1989) using again DNA-rRNA hybridization demonstrated that these strains were not closely related to the type species of *Oceanospirillum*, and they are currently classified in *Marinomonas*. This conclusion was later supported by 16S rRNA sequencing (Satomi et al., 1998; Satomi et al., 2001). More recently, Solano and Sanchez-Amat (1999) described a third species, *Marinomonas mediterranea*, which produces melanin.

When the genus *Marinomonas* was created, it could not be clearly differentiated from other groups of marine, Gram-negative bacteria solely on the basis of phenotypic characteristics. More-

over, while isoprenoid quinone content will distinguish *Marinomonas* from many other Gram-negative, aerobic bacteria routinely isolated from seawater, it will not distinguish species in the genera *Alteromonas*, *Pseudoalteromonas* and *Marinomonas* (Akagawa-Matsushita et al., 1992). The use of 16S rRNA sequence analysis or DNA-DNA hybridization readily resolves these taxa.

Phylogeny

All three species in the *Marinomonas* group are phylogenetically closely related, with a percent similarity of their 16S rRNA sequences greater than 95%. *Marinobacterium* spp. and *Neptunomonas* sp. are their closest relatives, with percent similarities slightly higher than 90%. Together with *Marinomonas* and *Oceanobacter*, these five genera formed a robust cluster in rRNA phylogenetic trees when different ingroup and outgroup sequences and parsimony and maximum likelihood analyses were used (J. M. González, unpublished observations). Similarly, analysis of the *gyrB* gene of *M. vaga* and *M. communis* supports a similar conclusion (Satomi et al., 2001). Thus, in spite of its apparent phenotypic similarities, species in the genus *Marinomonas* are not closely related to *Alteromonas* or *Pseudoalteromonas* (Fig. 1).

Taxonomy

Species of the genus *Marinomonas* were originally included in the genus *Alteromonas* because of their phenotypic similarities. When DNA-RNA hybridization data suggested that *Alteromonas* was paraphyletic, the genus *Marinomonas* was created (van Landschoot and De Ley, 1983). An additional species, *M. mediterranea*, has since been isolated, supporting the hypothesis that this genus is phylogenetically deep (Solano and Sanchez-Amat, 1999). The characteristics of the species in the genus are presented in Tables 2 and 8.

Data from Baumann et al. (1972) and Solano and Sanchez-Amat (1999).

Habitat

Marinomonas can be isolated from seawater. *Marinomonas communis* and *M. vaga* were isolated from open ocean seawater samples taken in the Hawaiian archipelago by Baumann et al. (1972). *Marinomonas mediterranea* and a number of uncharacterized *Marinomonas* strains

(Ansele et al., 2001) were isolated from coastal seawater.

Isolation

Marinomonas communis and *M. vaga* can be enriched by amending 500 ml of seawater with 25 ml of a solution of 1 M Tris-HCl (pH 7.5), 0.5

g of NH_4Cl , 38 mg of $\text{K}_2\text{HPO}_4 \cdot 7 \text{H}_2\text{O}$, 14 mg of $\text{FeSO}_4 \cdot 7 \text{H}_2\text{O}$, and 0.5 g of *m*-hydroxybenzoate. The culture is incubated at 20–25°C for up to 10 days. Isolates are obtained on Basal Medium Agar (BMA) plates containing 0.1% *m*-hydroxybenzoate (Baumann et al., 1984).

BMA

Tris-HCl (pH 7.5)	6.1 (or 12.1) g
NH_4Cl	1.0 g
$\text{K}_2\text{HPO}_4 \cdot 3 \text{H}_2\text{O}$	75 mg
$\text{FeSO}_4 \cdot 7 \text{H}_2\text{O}$	28 mg
Distilled water	500 ml
Artificial seawater	500 ml

Artificial seawater (ASW)

NaCl	23.4 g
$\text{MgSO}_4 \cdot 7 \text{H}_2\text{O}$	24.6 g
KCl	1.5 g
$\text{CaCl}_2 \cdot 2 \text{H}_2\text{O}$	2.9 g
Distilled water	1000 ml

Using a complex medium, Eilers et al. (2000) found that 6% of the isolates from a seawater sample taken directly from the North Sea were strains of *Marinomonas*. However, prefiltration through a 1.2 μm pore size filter favored the isolation of *Marinomonas*, and five out of nine isolates obtained under these conditions were close relatives of *M. communis*.

Additional isolates of *Marinomonas* spp. were obtained by Ansele et al. (2001) using media containing 1 mM of the osmolyte dimethylsulfo-niopropionate (DMSP). Either basal salts or f/2 media were used.

Basal Salts Medium

NaCl	2.34 g
$(\text{NH}_4)_2\text{SO}_4$	0.66 g
MgSO_4	0.096 g
CaCl_2	0.0333 g
Fe EDTA	3.27 mg

The pH is adjusted to 7.2 by adding potassium phosphate to a final concentration of 10 mM. Serial dilutions of seawater or sediment slurries are plated directly on this medium. In some cases, bacteria are first enriched in f/2 medium (Guillard, 1975) with 1 mM DMSP prior to plating.

Identification

Alteromonas and *Marinomonas* are phenotypically similar. *Marinomonas communis* and *M. vaga* may be distinguished from *Alteromonas* by their ability to utilize D-sorbitol, DL-malate, α -ketoglutarate, and *m*- and *p*-hydroxybenzoate, and inability to produce gelatinase or lipase. *Marinomonas mediterranea*, however, is unable to grow on *m*-hydroxybenzoate and has gelatinase and lipase activities.

Physiology

Marinomonas communis and *M. vaga* grow on D-fructose and D-glucose using the Entner-Doudoroff pathway. This pathway may be widespread among members of the large group of marine γ -Proteobacteria (Baumann and Baumann, 1973; Sawyer et al., 1977).

Applications

Marinomonas mediterranea is melanogenic (Solano et al., 1997; Solano and Sanchez-Amat, 1999; Solano et al., 2000) and produces polyphenol oxidase, an enzyme involved in melanin synthesis. These enzymes are commonly isolated from fungi and are of interest because of their potential biotechnological applications in polymerization of phenols, oxidation of xenobiotics, pulp bleaching, and oxidation of lignin substrates. *Marinomonas mediterranea* strain MMB-1 is one of the few bacterial isolates where laccase activity (one of the enzymes of the family of polyphenol oxidases) has been detected. Although not closely related, strain 2-40 has also been found to have polyphenol oxidase.

The Genus *Microbulbifer*

The genus *Microbulbifer* only contains one species, *M. hydrolyticus*, which was isolated by enrichment from coastal seawater (González et al., 1997). In addition, *Pseudomonas elongata* is closely related and should be reclassified into this genus (Anzai et al., 2000). The following properties are for both *M. hydrolyticus* and *P. elongata* and are characteristic of the genus. Cells are narrow Gram-negative rods, nonmotile, strictly aerobic, and oxidase and catalase positive (Tables 2 and 9). The temperature range for growth is 10–41°C, with an optimum at 25–37°C. Seawater-based medium is required for growth; the optimum NaCl concentration is 0.06–3.0%. Carbon sources utilized include carbohydrates, some amino acids and simple aromatic compounds such as vanillate and ferulate. Agar, cellulose, xylan, chitin, gelatin, starch and Tween 80 are hydrolyzed. Synthetic lignin is mineralized to a limited extent. The mol% G+C of the DNA is 58. The type species is *M. hydrolyticus* strain IRE-31 (ATCC 700072).

The cells possess vesicles or blebs derived from the outer membrane that may be an adaptation for degradation of polymeric compounds. These vesicles are attached to the cells or free in the culture medium and may function for the uptake of nutrients from the surroundings or involved in the degradation of insoluble compounds (Fig. 8). Similar vesicles have been

Data from González et al. (1997) and Humm (1946).

observed in both Gram-negative and Gram-positive bacteria (Forsberg et al., 1981; Antranikian et al., 1987; Gauthier et al., 1992; González et al., 1997; González and Weiner, 2000). In some cases, hydrolytic enzymes are associated with the vesicles (Forsberg et al., 1981). Unidentified bacteria inside decaying wood also produce these vesicles (Daniel et al., 1987; Singh et al., 1990).

Pseudomonas elongata and *M. hydrolyticus* share a number of traits (Table 9), including the ability to degrade polymeric compounds. *Pseudomonas elongata* was isolated because of its ability to degrade agar (Humm, 1946). *Microbulbifer hydrolyticus* does not degrade agar, but both organisms degrade other polymers including cellulose, chitin, starch and gelatin.

Fig. 8. (a) Negatively stained cells of *Microbulbifer hydrolyticus* strain IRE-31. The surface is covered by blebs (B) and vesicles (V) formed by extensions of the outer membrane (O) and S-layer (SL). (b) Ultrathin section of strain IRE-31 also showing vesicles (V). Reproduced with permission (F. Mayer, University of Göttingen, Germany).

They also produce exopolysaccharides and form long chains in broth, depending upon the growth conditions. Both strains were isolated from coastal seawater in environments where the salinity varies throughout the year and which receive a continuous load of plant-derived detritus.

In the case of the isolation of *M. hydrolyticus*, enrichment was carried out using lignin-rich byproducts of the pulp and paper industry. This organism dominated the enrichment after two weeks. Thus, polymeric waste products are suggested for the isolation of members of the genus from coastal seawater.

The Genus *Neptunomonas*

The first strains of this genus were isolated from heavily contaminated sediments by using naphthalene or phenanthrene as sole carbon sources (Geiselbrecht et al., 1996). The isolates were obtained after dilution (1:20, 000), suggesting that they were abundant in the sediment.

Neptunomonas is one of the few genera that have been isolated from the marine environment because of their ability to grow on poly-

Fig. 9. Negatively stained cells of *Neptunomonas naphthovorans* NAG-2N-126. Bar is 2 μ m. Reproduced with permission (J. T. Staley, University of Washington, and B. Hedlund, Universität Regensburg, Germany).

cyclic aromatic hydrocarbons (PAHs). The two characterized strains also grow on 2-methylnaphthalene or phenanthrene as the sole carbon source. The putative PAH dioxygenase genes from these two strains have also been sequenced, and they are more closely related to naphthalene and nitroaromatic dioxygenases from *Pseudomonas*, *Cycloclasticus* and *Burkholderia* than to biphenyl or monoaromatic dioxygenases (Hedlund et al., 1999).

Phylogenetic analysis of the 16S rRNA sequences groups this genus close to *Marinobacterium* spp., with similarities higher than 91%. *Neptunomonas*, *Marinomonas*, *Marinobacterium* and *Oceanobacter* also form a cluster with relatively high bootstrap values (Fig. 1).

The cells of *Neptunomonas* are Gram-negative, rods, motile by a single polar flagellum (Table 2; Fig. 9). They are facultatively aerobic, oxidase and catalase positive, able to grow on amino acids, carbohydrates, organic acids, and a few PAHs as the sole carbon source. They require sodium for growth. The mol% G+C of the DNA is 46 (thermal denaturation method). The type species is *Neptunomonas naphthovorans* strain NAG-2N-126 (ATCC 700637). The characteristics that distinguish *Neptunomonas* from phylogenetically closely related genera are listed in Table 2.

There is also some evidence that *Neptunomonas* spp. may be important in pristine environments. Clones of 16S rRNA genes related to *Neptunomonas* were retrieved without cultivation from microbial communities associated with sea ice (Brown and Bowman, 2001). The diversity of species in this genus remains to be determined because so few strains have been characterized.

The Genus *Oceanobacter*

Strains of this genus include the “H-1 group” of Baumann et al. (1972). Although cells are rod-shaped, they were originally classified in the genus *Oceanospirillum* as *O. kriegii* on the basis of immunological analysis of their superoxide dismutases and glutamine synthetases (Bowditch et al., 1984). Subsequently, DNA-rRNA hybridizations between this species and representatives of closely related organisms as well as sequence analysis of the 16S rRNA gene supported the reclassification to a new genus, *Oceanobacter* (Pot et al., 1989; Satomi et al., 2001). Consistent with this classification, members of this species grow on some carbohydrates (D-glucose, D-fructose and mannitol), whereas members of the *Oceanospirillum* sensu stricto do not. The mol% G+C of the DNA is also outside the range of *Oceanospirillum* sensu stricto. In addition, analysis of the 16S rRNA and *gyrB* gene sequences suggests a distant relationship between the genus *Oceanobacter* and the genera *Marinomonas*, *Marinobacterium* and *Neptunomonas* (Fig. 1).

The description of the genus is as follows: Gram-negative, straight rod, nonsporeforming, halophilic, aerobic, chemoheterotrophic, PHB-accumulating and oxidase-positive bacteria (Table 2). Motility is by means of flagella. Some carbohydrates are catabolized. In addition, some strains utilize simple alcohols and organic acids, such as ethanol and lactate, as well as betaine and aminobutyrate as sole carbon sources. These bacteria reduce nitrate to nitrite. The mol% G+C content of its DNA is 54–56. The ubiquinone type is Q-8 (Sakane and Yokota, 1994). The major nonpolar fatty acids in the phospholipids are C16:1 (36 %), C18:1 (27 %) and C16:0 (16 %; Sakane and Yokota, 1994). The major 3-hydroxy fatty acids are C12:0 (54 %), C16:0 (27 %) and C10:0 (19 %). Spermidine (0.84 $\mu\text{mol/g}$ of wet cells) and putrescine (0.03 $\mu\text{mol/g}$ of wet cells) were the only detectable polyamines (Hamana et al., 1994). The type species is *Oceanobacter kriegii* strain 197 (ATCC 27133). The differential characteristics of this genus with respect to other genera are shown in Table 2.

Pseudomonas halophila

Pseudomonas halophila was isolated from the highest dilutions of water samples taken from Great Salt Lake, Utah, that showed growth in media with acetate, glucose or glycerol (Fendrich, 1988). On the basis of the sequence of its 16S rRNA gene, *P. halophila* is distantly related to *Marinobacter* spp. (approximately 90% sequence similarity, Fig. 1). Even though the mol% G+C of the DNA is similar to that of

Marinobacter, the phenotype is substantially different. Thus, the 16S rRNA sequence similarity and differences in phenotypic characteristics suggest that *P. halophila* should be reclassified into a new genus.

Pseudomonas halophila is a Gram-negative, pleomorphic rod and motile by means of a single, polar flagellum. Cells are 0.8–1.0 μm wide by 1.5–5.0 μm long. It is a strict aerobe that uses a number of carbohydrates, organic acids and amino acids as carbon sources. It is catalase, oxidase and urease positive. It liquefies gelatin, and it is negative for arginine dehydrolase and for lysine and ornithine decarboxylase. Growth occurs between 0.12 and 19% NaCl, and the optimum concentration of NaCl is 5%. The temperature range for growth is 4–37°C, with an optimum at 28°C. The pH range for growth is 4.5–9.6 with an optimum growth at 7.0. The mol% G+C of the DNA is 57.

Strain 2-40 and the Shipworm Symbionts

Strain 2-40 (ATCC 43961) was isolated from the salt marsh because it can degrade agar and produce melanin pigments (Andrykovitch and Marx, 1988). On the basis of its 16S rRNA sequence, strain 2-40 is the most closely related to nitrogen-fixing symbionts that have been isolated from shipworms (Distel et al., 1991; Sipe et al., 2000), although the percent similarities are low (91–94%). These shipworms rely on the symbionts for the degradation of cellulose present in wood and for the acquisition of reduced nitrogen (Waterbury et al., 1983). The 16S rRNA gene sequence of strain 2-40 possesses 94% similarity to that of strain TBTC, isolated from the woodworm *Bankia setacea* (Sipe et al., 2000). These strains are also related to four strains from different genera of shipworms that also possessed similar phenotypic characteristics as well as identical 16S rRNA gene sequences (Waterbury et al., 1983; Distel et al., 1991). The percent similarities with these strains is >91%. Other symbionts from marine animals have also been found whose phylogeny remains to be determined (Haygood and Davidson, 1997).

The phylogenetic affinity of these strains to other genera is not clear since they appear equally related to the genera *Pseudomonas*, *Microbulbifer*, *Oceanospirillum* and *Marinobacter*. Strain 2-40 is a Gram-negative, pleomorphic rod, and motile by means of a single polar flagellum. The average cell width is 0.5 μm and the length is 1.5–3.0 μm , although in stressed cultures, filaments and coils are formed. It is a strict aerobe and catalase and oxidase positive. The temperature range for growth is 4–37°C. The

pH range for growth is 4.5–10. The sea salt concentration for growth is from 1–10%, with an optimum at 2.3–3.5%. The mol% G+C of the DNA is 47 (thermal denaturation method). Strain 2-40 is able to hydrolyze a number of polysaccharides, including agar. Strain 2-40 expresses polyphenol oxidase activity involved in the production of melanins during the late phase of growth. Like the enzyme from *M. mediterranea*, the enzyme from strain 2-40 has properties of tyrosinase and laccase (Solano and Sanchez-Amat, 1999). Although the tyrosinases have a wide distribution in different organisms, laccases are only found in fungi and higher plants and are involved in the polymerization and degradation of lignin. Thus, these enzymes have potential biotechnological application for the production of melanin pigments and in lignin degradation.

Serpens flexibilis: An Unusually Flexible Bacterium

ROBERT B. HESPELL

Habitats

Many eutrophic aquatic environments as typified by ponds or sewage lagoons harbor a wide variety of aerobic bacteria in the upper water layers. Thin, flexible bacteria such as spirilla, spirochetes, and *Serpens flexibilis* constitute a small fraction of the total microorganisms in these environments. The use of enrichment procedures to isolate these flexible bacteria usually is not successful because they are rapidly overgrown by the other bacteria, even when low-nutrient-containing media are used. Presumably, these flexible bacteria can compete in their natural environments because of factors such as high cell-surface to cell-volume ratios that allow for maximizing transport of nutrients, possession of chemotaxis mechanisms, and unusual motility properties that allow for movement through viscous solutions (Greenberg and Canale-Parola, 1977).

Isolation

Selective isolation

S. flexibilis can be selectively isolated by using procedures originally developed for isolation of thin spirilla and spirochetes (Canale-Parola et al., 1966). A small amount of pond water or mud slurry is placed in the center of a sterile cellulose filter disc (0.3 to 0.45 μm pore diameter) which has been placed on the surface of a petri dish containing isolation medium made with 1.0% agar. The disc is removed after aerobic incubation of the plate at 30°C for 6 to 12 h. After subsequent incubation of the plate for 2 to 4 days, a subsurface, whitish veil of growth develops. The organism can then be isolated by picking from the outer edge of the veil and streaking onto a second plate. Restreaking several times may be necessary to obtain pure, cloned cultures. An isolation medium that has been routinely used (Hespell, 1977, 1984) includes: yeast extract, 0.2 g; peptone, 0.1 g; 10 ml hay extract;

and 90 ml distilled water. The pH of the medium is adjusted to pH 7.0 with KOH prior to autoclaving. The hay extract is prepared by boiling 1.0 g of dried wheat or barley straw in 100 ml of distilled water for 15 min., cooling the mixture to room temperature, and decanting the fluid which is then clarified by centrifugation (8,000 \times g, 10 min).

Cultivation

Optimal growth yields (10^9 to 10^{10} cells/ml) and growth rates (20 to 30 min doubling times) of *S. flexibilis* can be obtained in a nutrient-rich medium such as LYPP medium (Hespell, 1977): 60% sodium lactate syrup, 1.0 ml; yeast extract, 0.3 g; peptone, 0.2 g; 0.2 M potassium phosphate buffer (pH 7.4), 10 ml; and 90 ml distilled water. Typical cultures consist of 250 ml of medium in 1-liter Erlenmeyer flasks shaken at 150 to 250 rpm at 30°C. The organism also can be grown on chemically defined media such as LCH, but the growth yields and growth rates are considerably lower. LCH medium consists of: 60% sodium lactate syrup, 1.0 ml; 0.4 g ammonium chloride; trace minerals (Hespell and Canale-Parola, 1970), 1.0 ml; 0.2 M potassium phosphate buffer (pH 7.4), 20 ml; and 78 ml of distilled water. Replacement of the ammonium chloride with an equivalent amount of peptone or Trypticase markedly stimulates growth. *S. flexibilis* will not grow on media having an initial pH of 5.8 or less, and optimal growth occurs when the initial pH is 6.8 to 7.2. During growth the pH of the medium rises to 9 to 11, and increased cell yields can be obtained by periodically lowering the pH by additions of weak HCl. Highest growth yields are obtained at 28° to 33°C, but no growth occurs at 10° or at 45°C.

Preservation of Cultures

Long-term storage of *S. flexibilis* can be accomplished by routine lyophilization of cultures. Alternatively, cultures can be stored in liquid nitrogen or ultracold (–75 to –85°C) freezers (Hespell and Canale-Parola, 1970).

Identification

S. flexibilis forms a subsurface veil of growth similar to that commonly observed with spirochetes. Microscopic examination of agar pieces removed from the leading edge of the veil show extremely flexible rods measuring about 0.3 by 10 μm long.

Often several cells are seen together and appear as “a pit of microbial snakes.” The cells display furious lashing motions and often tend to twist in and out of knot formations Fig. 1a. In liquid media, the movement is less dramatic. The long, slender cells usually move in straight lines displaying an overall flexing of the cell with the

Fig. 1. Phase contrast micrographs (Fig. 1a and b) and transmission electron micrographs (Fig. 1c and d) of *S. flexibilis* strain PFR-1. Cells from subsurface growth in agar media show rapid coiling movements (1a), whereas in liquid media (1b), cells display straight-line movement of flexing rods. Cells are quite flexible and are able to coil up (1c). They are motile by means of lateral flagella (1c) and polar tufts of flagella (1d). Cells are about 0.3 μm in diameter and 10 μm in length.

trailing cell tip having a vibrating motion Fig. 1b. No tumbling type of movement is observed. In stationary phase cultures, clumps of entwined cells are common, and often partially lysed cells, spherical cell bodies, are present Fig. 1c. Electron microscopy shows that cells typically possess a cluster of 4 to 10 flagella that are present at the tips of both cell ends; in addition, the presence of several lateral flagella randomly distributed along the cell body is not uncommon. Fig. 1d. The flagella are quite long (15 to 30 μm), have a constant waveform with a 0.3 μm amplitude, and possess the hook end and disk structure commonly observed with other bacteria.

In addition to its unusual motility characteristics, another key feature of *S. flexibilis* is the rather limited range of substrates that support its growth. Essentially, only lactate is catabolized and supports good growth. Limited growth can be obtained with α -ketoglutarate, acetate, or pyruvate. In the presence of peptone, the addition of glucose and a few other disaccharides results in about a doubling of cell yields over that observed in the absence of added substrates (2.0 to 6.0×10^7 cells/ml).

Colonies can be formed under aerobic conditions on media containing 2% agar. These are usually 3 to 4 mm in diameter, off-white to cream colored, and round with filamentous edges. The cells from colonies tend to be thicker (0.5 to 1.0 μm) and shorter (4 to 6 μm). Cell pellets from liquid cultures often are light pink to reddish in color, probably due to the presence of the cytochrome proteins; the pigments cannot be extracted with chloroform, methanol, or other solvents used to remove carotenoids. Whether taken from liquid cultures or colonies, cells are always Gram negative. Electron microscopy of thin sections of *S. flexibilis* shows that the cells have a classical double-track, Gram-negative cell structure (Hespell, 1977, 1984).

The phylogenetic status of *S. flexibilis* has been examined with the 16S rRNA oligonucleotide-cataloging technique. The results indicated that *S. flexibilis* has an S_{AB} of 0.9 with *Pseudomonas pseudoalcaligenes* (Woese et al., 1982). Woese et al. (1982) concluded that *S. flexibilis* was a close relative to *P. pseudoalcaligenes* and that it might be a variant pseudomonad that developed a defect in septum formation because *S. flexibilis* forms long cells with multiple cytoplasmic invaginations (Hespell, 1977, 1984). This 16S RNA phylogenetic placement of *S. flexibilis* has been confirmed by analysis of aromatic amino acid biosynthesis enzymes of *S. flexibilis* (Ahmad and Jensen, 1987). These studies indicate this organism belongs with subgroup Ia pseudomonads. While *S. flexibilis* shares a number of common features with *P. pseudoalcaligenes*, there are a number of distinct differences. Glucose and

many other sugars do not support the growth of either organism, and both organisms can grow with lactate, acetate, or pyruvate as energy sources. However, *S. flexibilis* does not grow with succinate, citrate, ethanol, fructose, or glycerol. The GC content of the DNA of *S. flexibilis* is 66 mol% (Hespell, 1977) and that of *P. pseudoalcaligenes* strains is 62 to 64 mol% (Palleroni, 1984). *S. flexibilis* differs from many *Pseudomonas* species in having multiple flagella and in lacking poly-B-hydroxybutyrate formation. At present, it would seem reasonable to consider *S. flexibilis* to be related to the pseudomonads. Because of its distinct features, this organism should probably be classified in its own genus (*Serpens*) and species (*flexibilis*) within the family Pseudomonadaceae. Although *S. flexibilis* strains have been isolated from several geographical locations (Hespell, 1977), detailed studies have not been done to determine whether enough differences exist to justify multiple species of *Serpens*.

Physiological Properties

S. flexibilis is a strictly aerobic bacterium and cannot grow anaerobically even in the presence of electron acceptors such as nitrate or nitrite. The organism displays an endogenous respiratory quotient (CO_2 released O_2 consumed) of 0.7 to 0.8, and this value increases to 1.56 in the presence of sodium lactate. Approximately 60% of the lactate catabolized is converted to carbon dioxide and about 30% is incorporated into cell material (Hespell, 1977). Growth on lactate-containing media results in production of trace amounts of formate and acetate. Cell extracts contain high levels of lactic acid dehydrogenase and enzyme activities associated with the tricarboxylic acid cycle. However, only trace levels of enzymes of the Embden-Meyerhof and hexose monophosphate pathways are present. Analysis of the peptidoglycan layer indicates that diaminopimelic acid is the main cross-linking compound, and the other constituents include alanine, glutamate, muramic acid, and glucosamine (Hespell, 1977). The peptidoglycan appears to be typical of that found in most Gram-negative bacteria.

The Genus *Psychrobacter*

JOHN P. BOWMAN

Introduction

The genus *Psychrobacter* includes bacteria which are Gram negative, spherical to rod-shaped, strictly aerobic, chemoheterotrophic, nonmotile, cold-adapted and osmotolerant. *Psychrobacter* species are primarily isolated from cold to warm, slightly to highly saline ecosystems ranging from glacial ice to sea-ice to chilled meat and fish to clinical samples (Table 1). The genus has only recently become better known following recent intensive bacterial isolation studies of various environments accompanied by 16S rRNA gene sequencing. From these studies it is clear that *Psychrobacter* is a widespread and evolutionarily successful group of bacteria, the biology of which may provide important insights into environmental adaptation and survival.

Taxonomy and Phylogeny

The genus *Psychrobacter* was originally described by Juni and Heym (1986) and included at that time one species, *Psychrobacter immobilis*. *Psychrobacter immobilis* strains were identified by a simple genetic transformation plate assay in which DNA isolated from strains were used to transform hypoxanthine-requiring or oxidase-negative mutants (Juni and Heym, 1980). Only DNA from *Psychrobacter* strains successfully transformed genetically closely related test strains that as a result regained the indicated phenotype. DNA from other taxa had no effect. The test was useful in sorting out the taxonomy of the large number of psychrotolerant *Achromobacter*-like and *Moraxella*-like strains isolated from fresh, frozen and irradiated food products, including fish (Georgala, 1958; Chai, 1981), poultry (Thornley, 1967; Lahellec et al., 1975), meat (McLean et al., 1951; Tiwari et al., 1972; Gill et al., 1977), some clinical samples (Bøvre, 1984; see Pathogenicity section), and including contaminants from cold-stored laboratory media.

Subsequently, rRNA-based analyses indicated the genus *Psychrobacter* belonged to the family

Moraxellaceae, which also includes the genera *Acinetobacter* and *Moraxella* (Rossau et al., 1991; Enright et al., 1994). The family Moraxellaceae forms a distinct branch in the class Gammaproteobacteria (Garrrity and Holt, 2001) and is most closely related to other aerobic chemoheterotrophic members of the Gammaproteobacteria including the families Halomonadaceae, Pseudomonadaceae and Oceanospirallaceae. The family does not include genus *Neisseria* (or its relatives *Kingella* and *Eikenella*), which has some morphological and phenotypic similarities with *Moraxella*. Instead, *Neisseria* and its fellow genera belong to class Betaproteobacteria and are thus completely unrelated to the Moraxellaceae.

The genus *Psychrobacter* has rapidly acquired species in the last few years, mostly from the increasing exploration of marine and polar ecosystems. The valid species as of 2003 included *P. immobilis* as the type species (Juni and Helm, 1986; for additional data, see Bowman et al., 1996), *P. faecalis* (Kämpfer et al., 2002), *P. fozii* (Bozal et al., 2003), *P. frigidicola* (Bowman et al., 1996), *P. glacincola* (Bowman et al., 1997a), *P. jeotgali* (Yoon et al., 2003), *P. luti* (Bozal et al., 2003), *P. marincola* (Romanenko et al., 2002), *P. okhotskensis* (Yumoto et al., 2003), *P. pacificensis* (Maruyama et al., 2000), *P. phenylpyruvicus* (Henriksen and Bøvre, 1968; Bøvre, 1984; Bowman et al., 1996), *P. proteolyticus* (Denner et al., 2001), *P. pulmonis* (Vela et al., 2003), *P. submarinus* (Romanenko et al., 2002) and *P. urartivorans* (Bowman et al., 1996; Table 1). The phylogenetic arrangement of these species is shown in Fig. 1. Some species occur in pairs, e.g., *P. submarinus* and *P. marincola*, possessing very similar 16S rRNA gene sequences. Therefore, 16S rRNA gene sequences can evidently only provide a preliminary assignment of species identity within the genus; phenotypic and other genotypic data are always necessary for reliable identification (see Identification section).

The species *P. phenylpyruvicus* was previously named “*Moraxella phenylpyruvica*” (Henriksen and Bøvre, 1968; Bøvre, 1984) and included isolates obtained from a variety of clinical sources.

Table 1. Habitats, suitable growth media, and incubation temperatures for routine cultivation.^a

Species	Known habitats	Media	Growth temperature (°C)
<i>P. glacincola</i>	Sea ice, and deep ice cores	MA	20
<i>P. immobilis</i>	Fish, chilled meat and blood products, ornithogenic soil, sea ice, cold seawater, and contaminants on lab media	Nutrient agar, TSA, and MA	25–30
<i>P. urativorans</i>	Antarctic ornithogenic soil, and chilled meat	TSA, and MA	20
<i>P. frigidicola</i>	Antarctic ornithogenic soil	MA	15
<i>P. proteolyticus</i>	Antarctic krill stomach	MA, and TSA + 2.6% NaCl	20–25
<i>P. phenylpyruvicus</i>	Internal organs, blood, cerebrospinal fluid of humans and various animals, and chilled meat and fish	BHI, nutrient agar + 5% horse serum, and Columbia blood agar	30–37
<i>P. faecalis</i>	Bioaerosol of pigeon feces	Nutrient agar, and MacConkeys agar	25–30
<i>P. luti</i>	Glacial mud, and seawater	TSA, and MA	25
<i>P. fozii</i>	Coastal marine sediment, and seawater	TSA, and MA	ND
<i>P. pulmonis</i>	Lungs of lambs	Columbia blood agar	30
<i>P. submarinus</i>	Seawater	MA	25
<i>P. marincola</i>	Internal tissues of ascidian (<i>Polysyncrator</i> sp.)	MA	25
<i>P. jeotgali</i>	Jeotgal, traditional Korean fermented seafood	MA	30
<i>P. pacifiensis</i>	Seawater, and Japan Trench	MA, and nutrient agar	25–30
<i>P. okhotskensis</i>	Icy seawater	MA	25

Abbreviations: MA, marine agar; TSA, trypticase soy agar; BHI, brain heart infusion; ND, not determined.

^aFor all validly described *Psychrobacter* species.

Results of 16S rRNA sequence analysis and general phenotypic traits indicated the species clearly belonged to *Psychrobacter* (Bowman et al., 1996). Suggestions for a new genus for *P. phenylpyruvicus* were proposed but never carried out (Pettersen et al., 1998) and in any case would be inappropriate inasmuch as the species is clearly embedded in a central phylogenetic position in the genus (Fig. 1).

Identification

In comparison to *Psychrobacter* (which is generally psychrotolerant, osmotolerant and nutritionally non-exacting), *Moraxella* and *Acinetobacter* are mesophilic, unable to grow at 4°C and are not halotolerant or halophilic. Neither of these genera occurs in marine habitats (Table 2). The genus *Moraxella* also has quite fastidious growth requirements and is generally only isolated from animal tissues and fluids where it exists most of the time in a benign parasitic relationship. *Acinetobacter* species on the other hand are widespread in soils, freshwater and wastewater ecosystems in which *Psychrobacter* is at best rare.

Phenotypic Characteristics

Psychrobacter species form cream or off-white, smooth, circular, convex colonies with a smooth margin and a buttery consistency. Some *Psychrobacter* isolates can be occasionally pale pink, pos-

sibly owing to accumulated cytochrome proteins (Bowman et al., 1997b). When grown under optimal conditions (see Growth and Isolation section), cells for all species are coccobacilli (typically 0.4–1.8 µm long and 0.4–1.6 µm wide). Juni and Heym (1986) described some strain differences including rod-like cells in chains, with the rods having either rounded or pointed ends. The cells are classified as nonmotile though they may possess numerous short fimbriae and move by “twitching” motility, as is typical for *Moraxella* and *Acinetobacter*. *Psychrobacter* species (also like other members of the family Moraxellaceae) do not form resting bodies (cysts, spores etc.), appendages, or other notable cellular architectural features. The cells though Gram negative can retain the crystal violet dye better than normal and so occasionally will stain Gram positive. Cells will however lyse rapidly in the presence of detergents (2% sodium dodecyl sulfate [SDS; w/v]) or strong alkaline solutions (3% KOH [w/v]) unlike most Gram-positive cells.

Psychrobacter species are distinctive as they can grow well at low temperature and can tolerate a wide range of salt concentrations (Table 3). Some species require or are strongly stimulated by sodium ions though most grow well without sodium. The variation in temperature requirements and ability to tolerate salt and ox bile salts are useful characteristics for distinguishing *Psychrobacter* species (Table 3). *Psychrobacter* species are neutrophilic growing best at pH 6.0–8.0 but not below pH 5.5 or above pH 9.0.

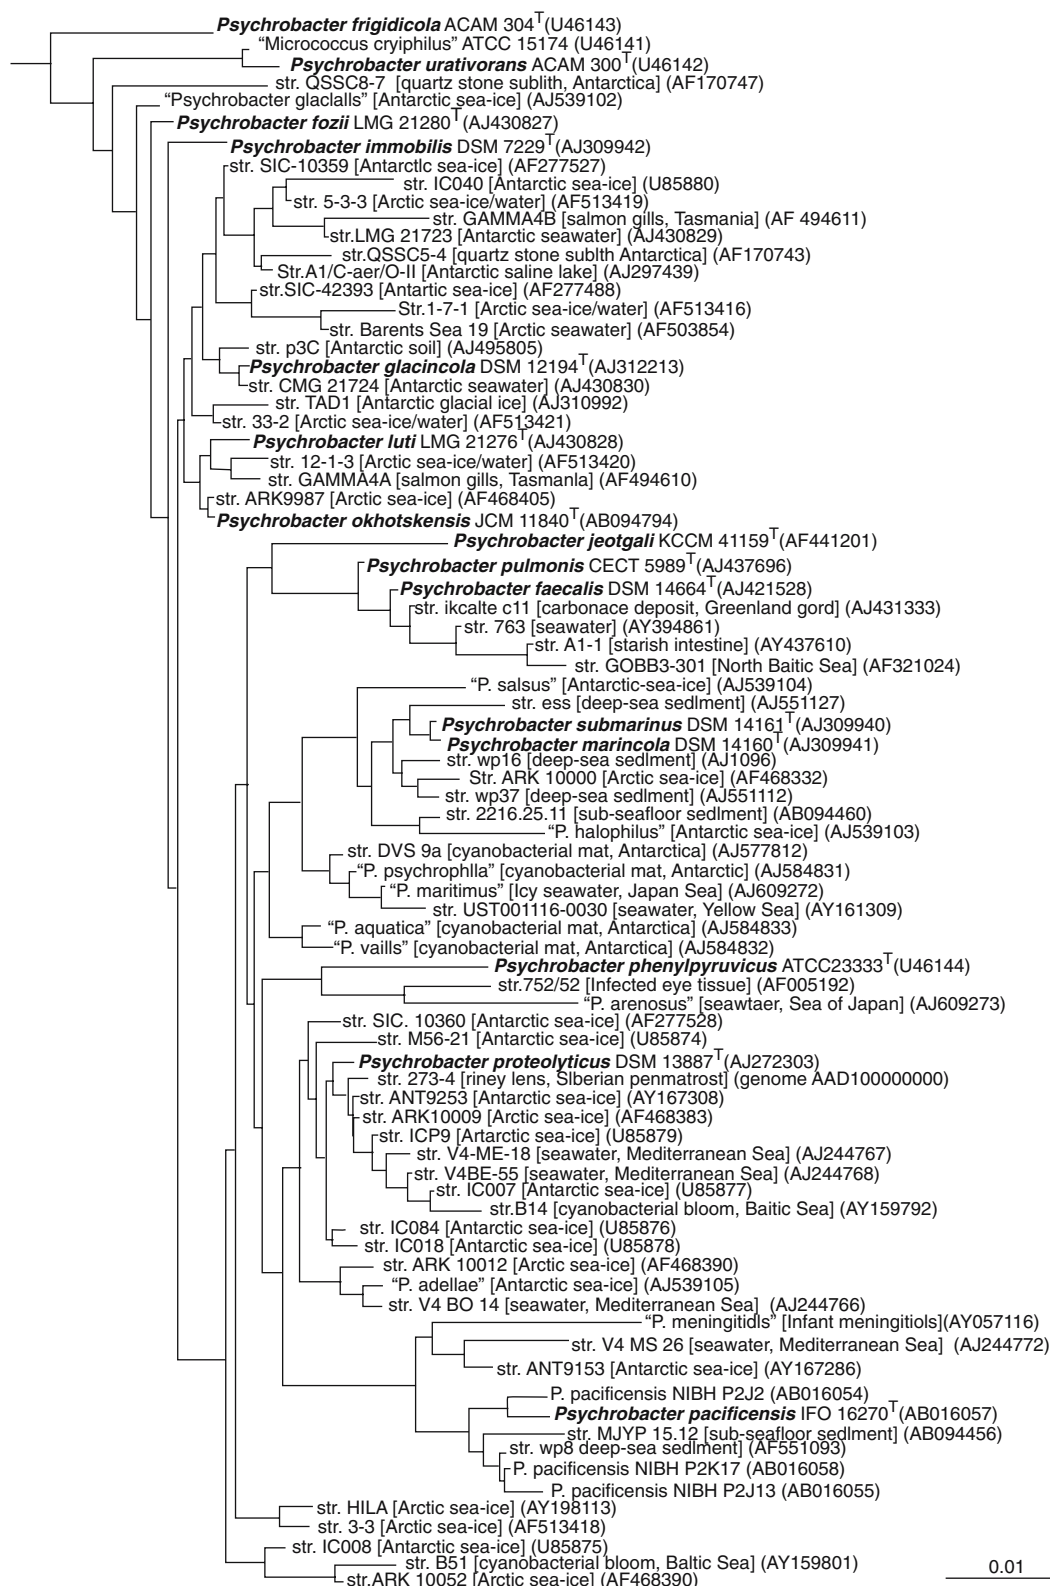

Fig. 1. A phylogenetic tree based on near complete and partial 16S rRNA gene sequences of the genus *Psychrobacter*. Branch lengths are based on maximum likelihood distances and the tree was constructed by the neighbor-joining method. Sequences of the type strains of validly named species are indicated in bold type. Names in quotation marks (e.g., "Psychrobacter glacialis" etc.) are as yet undescribed invalid species and in many cases may become new valid species of the genus in the next one to two years. Sequences indicated by "str." are either bona fide isolates or clones from published studies of the ecosystem indicated in brackets. The number in parentheses is the GenBank accession code for the given sequence. The scale bar at the base of the tree indicates a relative maximum likelihood distance of 0.01.

Table 2. Characteristics useful for differentiating *Psychrobacter* from its closest relatives *Moraxella* and *Acinetobacter*.

Trait	<i>Psychrobacter</i>	<i>Moraxella</i>	<i>Acinetobacter</i>
Oxidase test	+	+	–
Growth at 4°C	+	–	–
Growth in the presence of 6% NaCl	+	–	–
Complex growth requirements	V ^a	+ ^a	–
Occurrence in marine habitats	+	–	–

Symbols and abbreviations: +, trait is positive for most strains; V, test varies between strains or between species; and –, trait is negative for most strains.

^aSome *Psychrobacter* strains require yeast extract or horse serum for good growth including some but not all strains of *P. jeotgali*, *P. phenylpyruvicus* and *P. pulmonis*. *Moraxella osloensis* does not have complex growth requirements.

Table 3. Temperature and salt tolerance of *Psychrobacter* species.

Species	Growth temperature ^a (°C)				Salinity requirement and tolerance (% NaCl)						Tolerance to 5% ox bile salts
	4	25	30	37	0	1–6	8	10	12	15

<i>P. urativorans</i>	+	+	V/w	–	+	+	+	–	–	–	–

Symbols and abbreviations: +, most strains produce significant growth; V, trait is variable between strains; w, growth is weak (or not equivocal) for most strains; –, most strains do not grow; and ND, no data available.

^aAll *Psychrobacter* strains grow well between 7–20°C.

^bGrowth is stimulated by ox bile.

Psychrobacter species are always strictly aerobic showing no anaerobic growth under any condition and are almost always strongly catalase and cytochrome *c* oxidase positive. Tables 3 and 4 list some biochemical and nutritional characteristics that are useful for distinguishing valid *Psychrobacter* species. In general, *Psychrobacter* is relatively biochemically inert and will be unreactive in most of the popularly used commercial rapid tests (e.g., 20E API and 20NE API test strips, Vitek-Biomérieux). *Psychrobacter* species in general do not break down complex substrates such as polysaccharides; a minority may hydrolyze proteins (Denner et al., 2001; Table 4). Preferred carbon sources are organic acids and amino acids. Carbohydrates and other types of compounds are in general not utilized. *Psychrobacter* species often produce lipases and can break down a few substrates common in nature but not normally catabolized by most Gram-negative bacteria. One substrate is uric acid

(Bowman et al., 1996), which is the major nitrogenous end product of the metabolism of birds (high concentration in guano) and fish. Uric acid is derived from purine metabolism via hypoxanthine and xanthine and is broken down by the enzyme uricase oxidase to allantoin, which in turn is hydrolyzed to metabolites (3-phosphoglycerate and methylureate) that feed into the tricarboxylic acid cycle. Uric acid can serve as the sole source of carbon, nitrogen and energy for many *Psychrobacter* species (Bowman et al., 1996).

Chemotaxonomy

The major fatty acids in *Psychrobacter* include the monounsaturated lipids 16:1 ω 7c (palmiteic acid), 17:1 ω 8c (heptadecenoic acid) and 18:1 ω 9c (oleic acid). Oleic acid is particularly important (Table 5) and can be used as a determinant for

Table 4. Biochemical characteristics and DNA base composition of *Psychrobacter* species.

^aFatty acid nomenclature: Prefix “i” indicates *iso*-branched fatty acid. The first number indicates carbon chain length. The number following the colon is the number of double bonds present with the double bond position from the methyl end of the molecule indicated by the number following the “ω”. Suffix “c” indicates the fatty acid is of the *cis* isomer.

^bTrace fatty acids present at less than 0.5% of the total. Only major fatty acid components are shown. No data are available for *P. pulmonis*.

identification of the genus. The predominance in monounsaturated fatty acids is likely an adaptive factor for growth at low temperature since the low melting points of monounsaturated fatty acids helps maintain cytoplasmic membrane permeability at low temperature (Russell and Nichols, 2000). Other fatty acid components consistently detected include 18:0 (octadecanoic acid) and 3-OH 12:0 (3-hydroxy-dodecanoic acid). It should be noted that the presence of various minor components and the levels of components are significantly influenced by cultivation conditions and analysis methods used.

In *Psychrobacter* species, the major quinone is ubiquinone-8 (Q-8) and the major polyamines are spermidine and putrescine (Hamana and Takeuchi, 1998; Kämpfer et al., 2002). The polar lipids for the genus (phosphatidylethanolamine, phosphatidylglycerol and diphosphatidylglycerol) are typical of Gram-negative bacteria. *Psychrobacter* species also contain unidentified aminolipids, glycolipids and aminophospholipids (Denner et al., 2001; Kämpfer et al. 2002). Wax esters are also a common feature of the genus (Bowman et al., 1996) and the family Moraxellaceae (Bryn et al., 1977) but rare in other bac-

teria. Analysis of this lipid class is aided by the use of iatroscan thin layer chromatography, which allows separation of different derivatized and underivatized lipid classes on a thin rod of silica before volatilization and direct analysis by standard flame ionization gas chromatography (Volkman and Nichols, 1991). The wax esters are usually C₃₂–C₃₈ chains consisting of two fatty acids linked together by an ester bond. The production of wax esters may be tied to cold adaptation (Russell and Volkman, 1980), however the evidence for this is contradictory. The strictly mesophilic genus *Moraxella* is also rich in wax esters, which suggests wax esters may have another role in cell physiology. Levels and types of wax esters vary heavily between strains and species (Bowman et al., 1996).

Genotypic and Genomic Characteristics

Psychrobacter species have a DNA G+C content of 41–51 mol% (Table 4), which is similar to the other genera of the family Moraxellaceae. For *Moraxella*, the range is 40–47 mol% and for *Acinetobacter*, 38–47 mol% (Bøvre, 1984). The values are much lower than that of halomonads and pseudomonads (55–65 mol%).

Except for some of its cold-active enzymes, *Psychrobacter* has been the subject of very little genetic analysis (see Applications section). However, a strain of *Psychrobacter* (strain 273-4; most closely related to *P. proteolyticus*) isolated from an approximately 30,000-year-old Siberian permafrost core (Vishnivetskaya et al., 2000) has now a draft genome available Oak Ridge National Lab Genomics Web site (<http://genome.ornl.gov/microbial/psyc/>). The genome is 2.6 Mb long with 2603 predicted open reading frames (ORFs). The genome contains five copies of the ribosomal RNA coding operon. The sequences and predicted homologous genes are available on the listed Web site and at the National Collection of Biotechnology Information Web site.

Pathogenicity

Various *Psychrobacter* species have been found to occasionally cause infections in humans, animals and fish. The mechanisms of pathogenesis and epidemiology of pathogenic strains is essentially unknown. Transmission appears to be mainly in the form of environmental and nosocomial contact (e.g., breathing aerosols, wound infections, etc.). *Psychrobacter* is considered to be thus purely an opportunistic pathogen and

generally causes secondary albeit very serious infections. *Psychrobacter* has been found to cause rarely chronic peritonitis in humans (Daley et al., 1997) and these pathogenic isolates were designated “CDC group EO2” or “EO3” strains (Hudson et al., 1987; Moss et al., 1988). Various strains of *P. phenylpyruvicus* have been noted to cause infant meningitis and general bacteremia (Kikuchi et al., 1978; Bøvre, 1984; Lloyd-Puryear et al., 1991; Guttigoli and Zaman, 2000). *Psychrobacter* strains also cause ocular infections such as keratinoconjunctivitis (Gini, 1990), as well as endocarditis (Guttigoli and Zaman, 2000) and infective arthritis (Pérez et al., 2002). A *Psychrobacter* strain was implicated in a fatal infection of an acquired immunodeficiency syndrome (AIDS) patient (Lozano et al., 1994) and may cause lung infections in sheep (Vela et al., 2003). *Psychrobacter immobilis* strains can also be an opportunistic pathogen of farmed salmonid fish causing nonfatal secondary infections (fatal after 35 days) and a multitude of external and internal symptoms (Hisar et al., 2002). The antibiotic sensitivity of *Psychrobacter* strains is poorly known, but from the study of Romanenko et al. (2002), nonclinical strains were found to be resistant to most penicillin derivatives such as ampicillin and benzylpenicillin but sensitive to various aminoglycosides like kanamycin, neomycin and streptomycin.

Growth and Isolation

Psychrobacter species as a whole can be grown on various organic rich media commonly used in the laboratory (Table 1). Best results are obtained when these media are supplemented with 0.5–1.0 M NaCl, as some strains require sodium for growth. Incubation temperatures vary with the species, but almost all grow rapidly at 20–25°C (Table 1). Most species grow very well on marine agar (formula below). Excellent growth for most species occurs on nutrient and trypticase soy agar (TSA), especially when these media are amended with an extra 25 g of NaCl per liter. Some clinical species such as *P. phenylpyruvicus* and *P. pulmonis* include some fastidious strains, which show poor or no growth on the media mentioned. Instead these can be grown readily on brain heart infusion (BHI), Columbia blood agar, or nutrient and TSA supplemented with 5% (v/v) horse serum; after incubation in a humid atmosphere at 30–37°C. CO₂ is not required. All media can be purchased as dehydrated powders or in prepared form from various commercial vendors (e.g., Difco, Oxoid, Gibco, etc.).

Psychrobacter can be isolated from source material (see Habitat and Ecology section; Table

1) by direct plating onto appropriate media, typically marine agar for marine samples (seawater, sea-ice, sediment etc.), nutrient agar or TSA (amended with 6% NaCl to exclude non-halotolerant species) for terrestrial samples, and BHI or blood/serum agar for clinical specimens. Incubation at lower temperatures for samples from more temperate climes will help strongly select for *Psychrobacter* strains. Increasing NaCl concentration in media to about 0.5–1.0 M or greater can also increase selectivity. For ancient glacial ice, permafrost and sea-ice samples, pre-enrichment in standard or dilute media (such as 1/10 strength nutrient agar) at low temperatures (–5 to +5°C) enhances the probability of obtaining isolates. This enhancement does not occur if samples are simply directly plated (Bowman et al., 1997b; Vishnivetskaya et al., 2000).

Largish, cream colored, smooth colonies with a buttery consistency appearing on plates are characteristics presumptive of *Psychrobacter* strains. This can be further affirmed by cells having a coccibacilli morphology, Gram-negative or variable staining, and ability to grow at 4°C and tolerate ~6% NaCl (w/v). Species identification is possible by phenotypic characterization and lipid analysis (Tables 2–5), but 16S rRNA sequencing may be needed to get a definitive identification in some cases.

Marine Agar

Bacteriological peptone	5 g
Yeast extract	2 g
Ferric pyrophosphate	10 mg
Sea salts	35 g
Agar (optional)	15 g
Distilled water	1000 ml

Alternatively, replace sea salts and distilled water with natural seawater. Adjust pH to 7.3–7.5. Autoclave 121°C, 15 min.

The dehydrated medium known as “Marine 2216 agar or broth” is available from Difco Laboratories Inc.

Artificial Seawater (ZoBell, 1946)

NH ₄ NO ₃	2 mg
H ₃ BO ₃	27 mg
CaCl ₂	1.14 g
FePO ₄	1 mg
MgCl ₂	5.14 g
KBr	0.1 g
KCl	0.7 g
NaHCO ₃	0.2 g
NaCl	24.3 g
NaF	3 mg
Na ₂ SiO ₃	2 mg
Na ₂ SO ₄	4.1 g
SrCl	26 mg
Distilled water	1000 ml

Sea salts can also be purchased from chemical companies such as Sigma-Aldrich or from aquarium suppliers (the latter source is far cheaper and has a similar level of quality).

Preservation

Psychrobacter species form stable cultures and so can be maintained on agar plates or slants at normal growth temperature for 1–3 weeks or at 2–4°C for several months and potentially years. A temperature of 2°C is more ideal than 4–5°C, as fungal contamination is reduced and survival for cold adapted species is enhanced. Antifungal compounds, such as nystatin, should be added to media to prevent fungal contamination. Marine agar is an excellent media for agar storage for most species. Other media as noted in Table 1 and above should be used for species not able to grow well on marine agar. Low nutrient media or media containing large amounts of carbohydrates should never be used, as strains will rapidly lose viability. Heavy cell suspensions of *Psychrobacter* strains in broth mixed with 10–30% glycerol (v/v) can also be cryopreserved for several years by first pre-chilling on ice and then direct transfer of the suspensions to a –70°C or colder freezer. The suspensions can also be frozen directly in liquid nitrogen at –196°C. The cultures should be replaced on a regular basis (once every few years) if possible. Multiple vials of cryopreserved cells should be stored in one freezer in addition to a back-up set stored in a separate freezer. Lyophilization can also be employed using a variety of desiccants including skim milk, horse serum, or fetal bovine serum.

Habitats and Ecology

The genus *Psychrobacter* is found in a wide range of habitats (Table 1; Fig. 1). Most of the studied species have been isolated from cold, saline environments. For example, sea-ice and icy coastal seawater are excellent habitats for many *Psychrobacter* spp. (Bowman et al., 1997a; Bowman et al., 1997b; Bozal et al., 2003; Brinkmeyer et al., 2003; Yumoto et al., 2003). *Psychrobacter* strains have also been isolated from ancient glacial and ice sheet cores (Christner et al., 2003), supercooled water brine lenses in permafrost (cryopegs) derived from ancient marine layers of the Arctic Ocean (Vishnivetskaya et al., 2000; Gilichinsky et al., 2003), and accreted ice at the base of deep ice cores above seawater (Bowman et al., 1997a). In these apparently totally frozen locations, liquid can still occur at temperatures down to –10 to –15°C owing to the high salt (as high as 170–300 practical salinity units [psu]) concentrated by freezing. Carbon sources have been shown to be metabolized at –15°C in such places, and thus these exceptionally extreme environments have been suggested as useful models for astrobiology (Gilichinsky et al., 2003).

Psychrobacter species are also readily isolated from conventional marine environments including seawater (Venkateswaran et al., 1991; Kisand et al., 2002; Romanenko et al., 2002), marine sediment, and salt marshes where they may play a role in the breakdown of dimethylsulfoniopropionate (DMSP), a major osmolyte of algae (Ansedé et al., 2001). DMSP is broken down to dimethylsulfide, which enters the atmosphere where theoretically it influences weather by helping to initiate cloud formation. *Psychrobacter* species, such as *P. pacifiensis* also occur in sea depths of up to 6000 m (Maruyama et al., 1997; Maruyama et al., 2000) and subseafloor sediments (Inagaki et al., 2003); however, as far as is known *Psychrobacter* species do not possess adaptations to high pressure. *Psychrobacter* strains have also been shown to occur on unusual calcium carbonate column formations (called “ikaite tufa” in Greenland fjords; Stougaard et al., 2002). These strains could be seawater derived.

Psychrobacter spp. are also an important component of the food microbiota as mentioned previously in the Taxonomy section. This high prevalence is connected obviously to the combined psychrotolerance and osmotolerance of *Psychrobacter* species. *Psychrobacter* species are especially common on salted fish, chilled fish flesh, some shell fish, fermented seafood, chilled meat products of all varieties, and even cheese and raw milk (e.g., Gennari et al., 1992; Gennari et al., 1999; Prieto et al., 1992; Garcia-Armesto et al., 1993; Pin and Baranyi, 1998; Gonzalez et al., 2000; Pacova et al. 2001; Sakala et al., 2002; Vasquez et al. 2002; Bagge-Ravn et al., 2003; Bjorkevoll et al., 2003; Yoon et al., 2003). Though *Psychrobacter* spp. can spoil food, they are considered relatively minor spoilers compared to other bacterial species. In fish, *Psychrobacter* spoilage results in a musty off-odor, usually after the fish has been stored in the cold for 7–10 days. The offensive odors are not from compounds like trimethylamine *N*-oxide or H₂S, typically produced by major spoilers like *Shewanella* species. Also they do not produce histamines, which causes allergy problems for some consumers. Unlike most spoilers, *Psychrobacter* will tolerate salting and can survive storage in 25% NaCl for prolonged periods (Bjorkevoll et al., 2003). *Psychrobacter* appears to be mostly part of the normal surface microbiota of fish skin or the skin of various other animals. It can be found in the tissues of marine animals and sponges and on seaweeds and algae (e.g., Denner et al., 2001; Pukall et al., 2001; Romanenko et al., 2002). *Psychrobacter* also seem to be common in uric acid-rich soil derived from bird guano (e.g., Antarctic ornithogenic soils; Bowman et al., 1996) and in fecal bioaerosols (Kämpfer et al., 2002). *Psy-*

chrobacter species are otherwise absent from most soil environments unless they are exposed to continual low temperature and intermittent freezing (e.g., Wery et al., 2003).

Little is known specifically about the ecology of genus *Psychrobacter*. It is likely the genus has a role primarily as a commensal, degrading various dissolved organic carbon compounds other than sugars. The genus has evolved to tolerate low temperature and has a highly developed osmotolerance which allows it to be highly competitive and prevalent in many cold ecosystems.

Applications

Since *Psychrobacter* strains are thoroughly cold adapted, most biotechnological interest has been in novel cold-active proteins and enzymes which have broad applicability in industry and been extensively reviewed (e.g., Bull et al., 2000; Rothschild and Mancinelli, 2001). Important focus areas for cold-active enzymes include janitorial processes, modification of heat labile substances (such as various foods), and in energy conservation. Many of the proteins studied are quite novel. For example, *Psychrobacter* strains have been found to be a source for new protein families including cold-active glutamate dehydrogenases (Camardella et al., 2002) and anti-freeze proteins (Gilbert et al., 2004). Other cold-active enzyme studies have involved metalloprotease (Denner et al., 2001), lipase (Arpigny et al., 1997), and β -lactamase (Feller et al., 1997). *Psychrobacter* strains have also been shown to possess cold-active rolling circle recombination replication proteins (Duilio et al., 2001), including novel restriction endonuclease methyltransferases (Rina et al., 1997), which may have application in genetic modification technology.

The Genus *Leucothrix*

THOMAS D. BROCK

Leucothrix, a large-diameter, morphologically distinct, marine gliding bacterium, has been known in natural material since the time of Oersted in 1844, but its modern history began with the remarkable study Harold and Stanier published in 1955. In the introduction to their paper, Harold and Stanier state: “*Leucothrix* may be characterized succinctly as a chemoheterotrophic counterpart of the colorless sulfur-oxidizing organism *Thiothrix*. It has been observed on a few occasions...in the century since its original description, but the existing accounts of its morphology and development, based entirely on the examination of crude cultures, are either incomplete or inaccurate. Thanks to the ease with which it can be grown in pure culture, we have been able to determine its complete cycle of development, which includes a unique and hitherto undescribed process of gonidial aggregation to form many-celled rosettes.”

Leucothrix is fascinating not only because of its morphological distinctiveness, but also because of its large size and the ease with which it can be recognized in natural material. The organism seems to be entirely marine and is widespread as an epiphyte of marine algae (Fig. 1) (Brock, 1966). It also causes an extensive infestation of benthic crustacea and fish eggs (Johnson et al., 1971), and has become a problem in the field of aquaculture, especially in the artificial cultivation of lobsters. *Leucothrix* appears to be related to the cyanobacteria (Pringsheim, 1957; Raj, 1977), as determined by morphological similarities. However, no detailed studies of molecular relationships between *Leucothrix* and any cyanobacteria have been carried out, although the DNA base composition of *Leucothrix mucor* isolates, 47–49 mol% GC (Brock and Mandel, 1966), is similar to that of a number of filamentous cyanobacteria (Edelman et al., 1967), which cluster in the range 42–51 mol% GC. This similarity is made even more striking when it is compared with the wide variation in DNA base compositions of the unicellular

cyanobacteria (Edelman et al., 1967; Stanier et al., 1971) and with the wide variation found in the narrow-diameter gliding bacteria (Edelman et al., 1967).

Characteristics of *Leucothrix*

A simplified life cycle of *Leucothrix mucor* is given in Fig. 2. *Leucothrix* filaments are usually 2–3 μm in diameter and may reach lengths of 0.1–0.5 cm. The filaments have clearly visible cross-walls, and cell division is not restricted to either end but occurs throughout the length of the filament, as shown by autoradiography with tritiated thymidine (Brock, 1967). The free filaments never glide (thus distinguishing them from many other filamentous gliding bacteria, such as *Beggiatoa* and *Vitreoscilla*), although they occasionally wave back and forth in a jerky fashion. Under environmental conditions unfavorable to rapid growth, such as low temperature or low nutrient concentration, individual cells of the filaments become round and form ovoid structures called “gonidia,” which are released individually, often from the tips of the filaments (Fig. 3). The gonidia are able to glide in a jerky manner when they come into contact with a solid surface. They settle down on solid surfaces, synthesize a hold-fast, and form new filaments through growth and successive cell divisions. In nature, the gonidia are presumably elements of dispersal and enable the organism to spread to other areas. “Gonidia,” first used by Winogradsky (1888) for *Thiothrix*, is an unfortunate term because it implies some sort of unique structure. Actually, the gonidium of *Leucothrix* and *Thiothrix* is functionally and structurally equivalent to the hormogonium of the cyanobacteria, which is a motile structure of dispersal formed by the rounding up of a vegetative cell or group of cells in a filament.

Both Winogradsky (1888) for *Thiothrix* and Harold and Stanier (1955) for *Leucothrix* concluded that an apical-basal differentiation of filaments existed and that gonidia were formed primarily at the tips of filaments. Actually, such an apical-basal differentiation does not exist, and filaments do not taper. Careful examination of

Fig. 1. Filaments of *Leucothrix mucor* attached to fronds of the seaweed *Bangia fuscopurpurea* of various ages. (a) Very young, (b) young, (c) mature, (d) old. Nomarski interference contrast photomicrograph. Bars = 10 µm. (From Bland and Brock, 1973.)

Fig. 2. Life cycle of *Leucothrix mucor*.

even long filaments has never revealed narrower cell diameters at the ends than in the middle. Also, although gonidia may form primarily at the filament tips, this is by no means always the case. I have frequently seen whole filaments convert to a series of gonidia, with every cell in the filament rounding up.

Gonidia do not have a holdfast when first formed, but make it only in response to the proper environmental conditions. If there are high concentrations of gonidia, individual cells may aggregate, probably because of reciprocal attraction (chemotaxis?). They then synthesize a holdfast and the gonidia become adherent to each other by the holdfast and form a small rosette. A new filament grows out from each

gonidium, eventually resulting in a large and striking structure (Fig. 4). Rosette formation is found in both *Leucothrix* and *Thiothrix* and is an important means of distinguishing these organisms from many other filamentous bacteria.

Another interesting characteristic of *Leucothrix* is the ability of filaments to grow in such a way that knots are formed (Fig. 5) (Brock, 1964). Knots occur mainly when the organism is growing in rich liquid culture media, where filamentous growth is rapid. Knot formation is frequent enough in *Leucothrix* cultures to be used as a taxonomic characteristic. Since individual filaments do not flex or glide, a preformed filament cannot form a knot. Actually, knots seem to be

Fig. 3. Release of gonidia from filaments of *Leucothrix mucor*. Phase-contrast photomicrograph. Bar = 10 μm .

Fig. 4. Rosette composed of several *Leucothrix* filaments. Phase-contrast photomicrograph. Bar = 10 μm .

formed as part of the growth process, probably because growth occurs faster on one side of the filament than on the other, causing the filament to form a loop through which the tip of the filament can pass. Once the knot is formed it cannot be untied; rather, the cells in the region of the knot eventually fuse and form a bulb that is later released from the rest of the filament. As a result, the long filament is separated into two shorter filaments. Knots are also seen occasionally in *Thiothrix* filaments in sulfur springs, where large accumulations of these organisms appear, and in *Leucothrix* populations in nature (T. D. Brock,

Fig. 5. Knots formed by filaments of *Leucothrix mucor*. Phase-contrast photomicrograph. Bar = 5 μm . (From Brock, 1964.)

unpublished observations). All of the structural features of the *Leucothrix* life cycle can be observed not only in culture but also in natural material, especially when Nomarski optics are used to examine the surfaces of algal fronds (J. A. Bland, personal communication).

Fig. 6. Electron micrographs of thin sections of *Leucothrix mucor*. (a) Portion of a multicellular filament. (b) Filament in early stage of gonidial formation, showing rounding up of the cells. Note that there is no change in the ultrastructure of the wall. (c) A single gonidium. The gonidia retain all of the envelope structures observed in filaments. (d) Thin section through a rosette. The holdfast material (hf) is an electron-dense material surrounding the cells. (a, b, d) Bars = 1.0 µm; (c) bar = 0.2 µm. (From Brock and Conti, 1969.)

An electron microscopic study of *Leucothrix* was carried out by Brock and Conti (1969), and some of the structural features of the organism are seen in Fig. 6.

Taxonomy of *Leucothrix*

The question of the physiological or taxonomic relationship between *Leucothrix* and *Thiothrix* has not been resolved. A *Thiothrix* filament or rosette that has lost its sulfur granules cannot be distinguished from *Leucothrix*. Harold and Stanier (1955) placed pure cultures of *Leucothrix* in sulfide-containing sea water and examined them at intervals for the presence of intracellular sulfur granules. No evidence of sulfur accumulation was obtained; this was also my experience with one pure culture. However, Kjell Eimhjellen of the Technical University in Trondheim, while working in C. B. van Niel's laboratory at Pacific Grove, California, was successful in attempts to show oxidation of hydrogen sulfide by *Leucothrix*. In his words (personal communication, 26 March 1970):

Leucothrix mucor (the strains I isolated all corresponded very well to the description of Harold and Stanier) pre-grown on the usual media, can be made to oxidize sulphide when exposed to an atmosphere of hydrogen sulphide and oxygen, very much in the manner of *Sphaerotilus* observed by Skerman. Based on comparison of the pictures published by Skerman, *Leucothrix*, however, seemed to have a greater ability to oxidize sulphide. The filaments of *Leucothrix* often had a very heavy accumulation of internal S-globules, making the filaments resemble the very best rosettes of *Thiothrix* you can find in nature. After extensive washing of such cells to remove chemically produced sulphur, resuspension in low-sulphate media and incubation by gentle shaking, the internal S-globules disappeared and copious amounts of sulphate could be isolated from the supernatant. The sulphide oxidation was never followed manometrically, but I did a great many measurements of the ability of *L. mucor* to oxidize thiosulphate. Every time the oxidation would proceed quantitatively to tetrathionate and in a fair number of experiments the oxidation went further to a complete oxidation to sulphate. I could never clear up the reasons for this inconsistency. In separate experiments, the presence or absence of carbon dioxide seemed to make no difference on the total oxygen uptake, indicating no use of thiosulphate as electron donor for CO₂ fixation. . . . My conclusion is that the strain of *L. mucor* I used had the enzymatic capability to oxidize

sulphide, sulfur and thiosulphate, all compounds being oxidized to sulphate, but no evidence for any energy link has been found.

It seems likely from a comparison of the results of Eimhjellen with those of Harold and Stanier (1955) that strain differences exist and that some strains of *Leucothrix* are able to deposit elemental sulfur. Further work on this problem would be of considerable interest.

Only a single species of *Leucothrix* is currently recognized, *Leucothrix mucor* (Brock, 1974). Pringsheim (1957) described *L. cohaerens* as a second species, based on cell diameter and filament length, but there is considerable variation in these properties even in a single pure culture, and since Pringsheim's isolates are no longer available, it seems preferable to maintain only a single species. Kelly and Brock (1969b) showed by physiological and molecular techniques that a wide variety of *Leucothrix* isolates, obtained from coastal areas around the world, were very similar. Of 35 strains characterized, all had a pH optimum of 7.6 and a salinity optimum of 30 parts per thousand. (The GC content of the DNA varied only over the narrow range of 48–51 mol% GC. Temperature optima of all strains were in the range 25–30°C, with a maximum of 33°C. Most strains showed a minimum temperature for growth of 0–2°C, although one strain, isolated from a tropical area, had a minimum temperature for growth of 13°C and hence was more stenothermal. Growth factor requirements were determined for all 35 strains. Most had no growth factor requirements and were able to grow heterotrophically on a simple glutamate culture medium, but 2 strains required thiamine, 1 strain (the warm water isolate) required vitamin B₁₂, and 3 strains showed a partial aspartate requirement. All the strains possessed the array of morphological characteristics typical of the species: filaments, gonidia, rosettes, knots, and bulbs. Brock described a neotype strain of *Leucothrix mucor* and listed its characteristics as follows.

Morphology

Filaments are of variable length, often much greater than 100 µm, with a diameter of 2–3 µm. Sulfur granules are not formed. True knots are usually formed by pure cultures when growing in organically rich media. Filaments are colorless, unbranched, and nonmotile (although occasionally waving back and forth) and lack a sheath, although cells in regions of a filament may become emptied of their contents and give the appearance of a sheath. Filaments often grow intertwined or in dense tangles. Swollen cells often form at random along filaments. Larger

structures (bulbs) usually form in knotty cultures, probably as a result of fusion of cells in the region of the knots. Filaments are attached to solid substrates by means of an inconspicuous holdfast that can be seen by staining with primulin and viewing with blue light in a fluorescent microscope; the holdfast fluoresces red. Individual filament cells round up and form ovoid to spherical gonidia that acquire a jerky gliding motility when released. Gonidia frequently aggregate in cultures, probably chemotactically, to form rosettes.

Nutrition

Most strains do not require growth factors. They grow on glutamate as sole source of carbon, nitrogen, and energy. They also use sugars, organic acids, and other amino acids as carbon and energy sources and NH₄⁺ as nitrogen source. *Leucothrix* requires Na⁺ for growth (optimum 1.5% NaCl, minimum 0.3%, maximum 7%).

Relation to Temperature

Optimum 25–28°C; maximum 32–35°C. *Leucothrix* grows at 0°C to form visible colonies within 1–2 weeks.

Relation to O₂

Obligately aerobic.

Habitats

As noted in the Introduction, *Leucothrix* appears to be strictly a marine organism. It is widespread as an epiphyte on marine algae and also occurs as an infestation of benthic crustacea (Johnson et al., 1971). On seaweeds, it appears most commonly in temperate waters (Kelly and Brock, 1969a), where densities are often quite high. In a detailed study at Friday Harbor, Washington, Bland and Brock (1973) made quantitative microscopic determinations of *Leucothrix* densities on a number of seaweeds. The organism was found on a variety of red, green, and brown algae, but was much more abundant on intertidal than on subtidal algae. The red alga *Bangia fuscopurpurea*, a filamentous species living in the high intertidal region, was unusually heavily colonized, with *Leucothrix* populations 10–30 times larger than those on other algal species in the same locations. Because of its high intertidal location, *B. fuscopurpurea* is exposed to air for fairly long periods during each tidal cycle. *B. fuscopurpurea* mats, dried during low tide, showed greater *Leucothrix* populations on the underside of the mats than on the top, presumably because

the underside of the mats retained moisture longer. Examination of *B. fuscopurpurea* filaments of various ages showed that there was a continuous increase in the *Leucothrix* density with algal age, a finding that suggested growth on the alga itself. Using axenic two-membered cultures in an autotrophic medium with several red algae (including *B. fuscopurpurea*) and *L. mucor*, Brock (1966) showed that *Leucothrix* could grow on nutrients produced or liberated from the alga. Bland and Brock (1973) used artificial substrates and a variety of ecological studies to demonstrate that in nature *Leucothrix* obtained most of its nutrients from the alga and not from the sea water. Details of these ecological experiments and a review of other literature on the ecology of *Leucothrix* should be sought in the original paper (Bland and Brock, 1973).

Brock (1966) thought that *Leucothrix* was more abundant on seaweeds in temperate than in tropical waters (see also Kelly and Brock, 1969c), but Johnson et al. (1971) found *Leucothrix* to be abundant on tropical algae in the Pacific. Brock (1966) also concluded that *Leucothrix* was more abundant on algae in habitats of high aeration, such as open, exposed coasts and areas with heavy tidal currents. Since *Leucothrix* is an obligate aerobe, the preference for highly aerated habitats is not surprising. The finding that *Leucothrix* prefers algae in the intertidal rather than the subtidal zone is in keeping with this hypothesis, although there are, of course, factors other than aeration that differ in these two kinds of habitats. A survey of marine habitats showed that *Leucothrix* was worldwide in distribution (Kelly and Brock, 1969b), including the southern hemisphere (Brock, unpublished observations in New Zealand).

An authentic freshwater strain of *Leucothrix* has never been isolated, although *Thiothrix* occurs in both fresh and marine waters. Microscopic surveys of freshwater algae, even freshwater red algae, have never shown any indication of the presence of *Leucothrix* (Brock, unpublished observations), although Eikelboom (1975) found a number of *Leucothrix*-like organisms in activated sludge (see also van Veen, 1973; Sladka and Ottova, 1973). However, because there are various other filamentous septate bacteria, positive confirmation of freshwater *Leucothrix* will require isolation in pure culture and demonstration of the various stages of the life cycle, especially gonidia and rosettes.

Isolation

Harold and Stanier (1955) first isolated *Leucothrix* from crude enrichment cultures of rotting

seaweeds, but such cultures are generally grossly contaminated and purification of *Leucothrix* is often difficult. A more effective way of isolation (true for many other gliding filamentous bacteria as well) is to avoid enrichments completely and carry out a direct, single-colony isolation from natural material. This operation is made especially easy with *Leucothrix* when it is growing on relatively clean seaweeds, because on such samples, motile unicellular contaminants (the organisms presenting the greatest difficulty in isolation) are relatively small in number.

Any marine-type seawater base can be used in the formation of a culture medium; natural sea water (filter-sterilized) itself can be used, but pH control and avoidance of metal precipitation are easier in a Provasoli-type culture medium (Provasoli, 1963). The following salts formulation (Brock, 1966) proved quite effective:

NaCl	11.75 g
MgCl ₂ · 6H ₂ O	5.35 g
Na ₂ SO ₄	2.0 g
CaCl ₂ · 2H ₂ O	0.75 g
KCl	0.35 g
Tris(hydroxymethyl) aminomethane	0.5 g
Na ₂ HPO ₄	0.05 g
Deionized water	1 liter
Adjust to pH 7.6.	

The low phosphate concentration of this salts base is critical, as media of normal phosphate levels are inhibitory. Most strains have no vitamin requirements and use glutamate as the sole source of carbon, nitrogen, and energy, so that this salts medium with 0.1% monosodium glutamate (MSG) and 2% agar (to inhibit swarming organisms) will permit the isolation of *Leucothrix* from most materials. Other useful media include 0.1% MSG plus a vitamin mixture, 0.1% MSG plus 0.01% yeast extract, and 0.1% tryptone plus 0.1% yeast extract. In the initial isolation step, it is best to keep the organic concentration of the medium low to avoid problems with overgrowth by unicellular bacteria.

For isolation, single algal filaments are streaked directly (or after washing in sterile salts) onto agar plates, which are incubated at 20–25°C overnight. Within 12–18 h after streaking, the plates are examined under 125× magnification (10× eyepiece with a long working distance, phase-contrast objective is best) for the presence of characteristic *L. mucor* colonies, which have a coiled rope or thumbprint morphology. These colonies are picked by touching them with a sterile insect pin and transferring them to fresh agar plates of the same composition. It is important that colonies be identified early after inoculation, before the plates are overgrown. Although a dissecting microscope can also be used to locate *Leucothrix* colonies

(Harold and Stanier, 1955), I have found that a 10× microscope objective (12.5× eyepiece) is better for locating colonies when they are very small (before they are overgrown). By using these procedures, it has been possible not only to isolate *Leucothrix* from seaweed from a wide variety of habitats, but also, with very clean material, to obtain growth of *Leucothrix* colonies directly from filaments still attached to seaweed fronds. In this way, the precise habitat from which the isolate was obtained is known; such information is of considerable value in studies on the molecular evolution of *Leucothrix* (Kelly and Brock, 1969b).

During transfer of colonies to liquid culture, it has often been observed that only very slight growth, if any, occurred after several days when an inoculum was transferred from agar to 100-ml liquid cultures; but when the inoculum was placed in a small volume of medium, such as 1–2 ml, heavy growth occurred overnight. Such small cultures could be easily used as the inoculum for large flasks and permitted the buildup of large-volume cultures. In liquid medium, growth is best when the flasks are shaken gently, such as on a wrist-action shaker or slowly on a rotary shaker. With the latter kind of shaker, growth rate is increased if the flasks contain small internal baffles, made by pushing in the sides of the flasks during heating with an oxygen flame.

For growing high-density cultures, a medium containing 1% MSG, 0.2% sodium lactate, and 0.01% yeast extract has proved quite suitable, the yeast extract providing growth factors needed by some strains. The sodium lactate was found to substantially increase the yield of most cultures.

Identification

Leucothrix is identified simply on the basis of morphological examination with the light microscope. The filaments are of large diameter (greater than 2 µm; average, 2–3 µm), and each filament is composed of short cylindrical or ovoid cells, with cross-walls clearly visible. The filaments are colorless, unbranched, and of variable length, often very long. The filaments do not taper, but there may be variation in diameter along the length of the filaments. The filaments do not glide, although they may wave sporadically from side to side. Rosette formation is a key diagnostic characteristic. Without observation of the presence of rosettes, it is not possible to easily identify an isolate as *Leucothrix*. Conversion of cells in filaments into gonidia may result in the formation of chains of spherical cells, or gonidia may form only at the ends. The gonidia exhibit

gliding motility, although the rate of motility is generally so slow that gliding itself is not a good diagnostic characteristic. To study gonidia formation, gliding, and aggregation, slide cultures are preferable; chambers that permit examination with 10–25× objectives should be used. Growth in such chambers is better if a considerable air space is left along one side, since *Leucothrix* is an obligate aerobe.

Filaments in culture often form true knots, and the presence of knots in a culture may be considered indicative of *Leucothrix* even without the formation of rosettes. However, the density of knots is never high, and a number of microscopic fields must be searched to ascertain if knots are present. Knot formation is most frequent when growth occurs to a high cell density in a relatively rich culture medium.

All strains that have been isolated are marine and require NaCl for growth; but, since freshwater strains could theoretically exist, NaCl requirement should not be considered a diagnostic characteristic. The GC content of the more than 30 strains examined ranged from 46 to 51 mol%, a relatively narrow range. Only one species is recognized (Brock, 1974), *Leucothrix mucor*.

Acknowledgment The preparation of this paper was supported by the College of Agricultural and Life Sciences, University of Wisconsin.

The Genus *Lysobacter*

HANS REICHENBACH

The species classified in the genus *Lysobacter* are Gram-negative rods that move by gliding. The cells are slender and cylindrical, with rounded ends (Figs. 1 and 2). They typically measure $0.4\text{--}0.6 \times 2\text{--}5\text{ }\mu\text{m}$, but in the population there are also always long to very long (up to $70\text{ }\mu\text{m}$) cells and filaments. The cell shape and the occurrence of long cells are both very characteristic for the genus. *Lysobacter* cells resemble the vegetative cells of certain myxobacteria, specifically of the genera *Polyangium* and *Sorangium*, with which the lysobacters were confused for many years. They also share with the myxobacteria a high GC content of their DNA of 65 to 70 mol%. Due to the gliding movements of the cells, the colonies of *Lysobacter* are spreading or swarming on solid media and may become very large and extremely thin (Figs. 3 and 4). Sometimes the organisms produce copious amounts of slime, and the colonies then become thick and deliquescent, but colonies with a wrinkled and dry surface also occur. *Lysobacter* colonies may be white or cream-colored but often they are greenish-yellow, purplish-red, or brown, although their color is often rather pale. Some strains produce an unpleasant odor reminiscent of certain pseudomonads or of pyridine. In agitated liquid cultures, the lysobacters grow as homogeneous cell suspensions, but, as with all gliding bacteria, the suspended cells are unable to translocate. The *Lysobacter* species live in soil, decaying organic matter, and fresh water, sometimes in large populations. Many strains are of considerable ecological and biotechnological interest as producers of exoenzymes and of antibiotics.

The genus *Lysobacter* was defined by Christensen and Cook (1978) who also described the presently recognized species and created a new family, Lysobacteraceae, and a new order, Lysobacterales. The organisms thus classified had already been known, however, for a long time under various names, such as *Cytophaga*, *Sorangium*, and *Myxobacter* (the latter an obsolete myxobacterial genus), which were usually pre-

sented with some doubts of the investigators concerning the classification of their strains. The first lysobacter in the scientific literature may have been *Flexibacter albuminosus* (Soriano, 1945, 1947), which had the cell size and shape of a lysobacter and formed thick dirty-white colonies and a diffusible dark pigment. But the description is not accurate enough and the strains are no longer available so that the question cannot be decided. The first unequivocal *Lysobacter* strain was a chitinolytic strain first tentatively identified as *Cytophaga johnsonae* Veldkamp, (1955). It is deposited at the National Collection of Industrial Bacteria (NCIB no. 8501) and was originally listed as a *Polyangium* species. The strain has a GC content of 71 mol% (T_m) and was noted as an unusual case of a cytophaga with a high GC content (Mitchell et al., 1969). Other early strains that later turned out to be lysobacters are: 1) “myxobacter” or “*Sorangium*” strain 495, which was studied because it attacks nematodes (Katznelson et al., 1964) and various bacteria (Gillespie and Cook, 1965) and contains very interesting proteases (for details, see “Practical Aspects,” this chapter); the strain also produces two peptide antibiotics, the myxosidins (Clapin and Whitaker, 1976, 1978); 2) “Myxobacter” AL-1, which became of interest because it digested cells and cell walls of *Arthrobacter crystallopoietes* (Ensign and Wolfe, 1965) and which was later found to excrete two unusual proteases; 3) “*Sorangium*” 3C, producer of the wide-spectrum phenazine antibiotic myxin (Peterson et al., 1966); 4) “*Cytophaga*” L1, (NCIB 9497) for which a patent was filed for a number of unusual enzymes of practical interest, e.g., keratinase, laminarinase, and chitinase (Brit. Pat. 1,048,887, 23 November 1966), and 5) “*Cytophaga johnsonae*” (ATCC 21123), originally isolated because of its lytic enzymes at Kyowa Hakko in Japan (Jap. Pat. 06624, 1969), and from which the new quinoline antibiotic G1499–2 was obtained (Evans et al., 1978). In addition a number of lysobacters, usually labeled “myxobacters,” were isolated because they attacked cyanobacteria and green algae and multiplied spectacularly

Fig. 1. Phase contrast photomicrographs of *Lysobacter*. (a), (b), and (d) *L. antibioticus* strain UASM L17 (= ATCC 29480) grown on CY agar (0.3% Casitone, 0.1% yeast extract) for 3 days at 20°C. Typical is a fairly regular cylindrical cell shape and a substantial variation in cell length. (c) *L. enzymogenes* type strain UASM 495 (= ATCC 29487), grown on VY/2 (yeast) agar for 13 days at 30°C. (a) Bar = 20 μm. (b), (c), and (d) Bars = 10 μm.

Fig. 2. Phase contrast photomicrographs of slime structures produced by *Lysobacter*. (a) *L. antibioticus* strain UASM L17 grown on CYG2 agar (CY agar plus 0.3% glucose) for 3 days at 20°C. For photography, the cells were transferred to a thin film of water agar. A network of slime threads is clearly visible. Bar = 10 μm. (b) The cyanobacteriolytic lysobacter of Shilo (1970). Edge of a colony on Shilo's (2% Casitone) agar in a chamber culture. Slime trails have been laid by the cells during their gliding movements. Bar = 10 μm.

during algal blooms. Thus, “myxobacter” FP-1 specialized on cyanobacteria (Shilo, 1967, Shilo, 1970); “*Cytophaga*” N-5, later renamed “myxobacter” 44, lysed cyanobacteria and green algae (Stewart and Brown, 1969); “myxobacters” 45 and 46, which with “myxobacter” 44, “*Sorangium*” 3C, and “myxobacter” AL-1, have an uncommonly high GC content of around 70 mol% (Stewart and Brown, 1971); and the cyanobacterium-lysing bacteria with a high GC content isolated from British waters, e.g., strains CP-1, -2, -3, and -4 (Daft and Stewart, 1971; Daft et al., 1975).

The phylogenetic position of the genus *Lysobacter* remained obscure until recently. To the

early investigators, gliding motility suggested some relationship with other, existing groups of unicellular gliding prokaryotes, specifically the myxobacteria and the cytophagas (Reichenbach, 1981). This is reflected by the names given to the strains isolated at that time. But as was already correctly anticipated in the taxonomic description of the new organisms, these bacteria form a group of their own (Christensen and Cook, 1978). Later, 16S RNA studies demonstrated that *Lysobacter* is relatively closely related with the xanthomonads and belongs to the gamma-3 branch of the purple bacteria (Woese et al., 1985) known today as the class Proteobacteria (Stackebrandt et al., 1988).

Fig. 3. The *Lysobacter* colony. Bars = 1 mm. (a), (b), and (c) *L. antibioticus* strain UASM L17 grown on different media for 7 days at 20°C: (a), on CA2 agar (0.075% KNO₃, 1% glucose); (b), on MYX agar (0.5% Na glutamate, 0.1% yeast extract, 0.2% glucose); and (c), on CY agar. (d) and (e) the chitinoclastic strain (NCIB 8501) of Veldkamp (1955): (d) grown on CA2 agar; (e) grown on CY agar; both 7 days old (20°C). (f) *L. enzymogenes* strain UASM 495 grown on CA2 agar for 7 days at 20°C. In all cases, the colonies are spreading, but they still are rather small after 1 week. On diluted CA2 agar containing nitrate as the sole nitrogen source, the swarm colonies of all three strains remain rather delicate. In (e), small crystals can be seen within the colonies, as is often the case with lysobacters.

Fig. 4. *Lysobacter antibioticus* strain UASM L17. Edge of a swarm colony showing the typical flamelike protrusions. CY agar, 7 days at 20°C. Bar = 1 mm.

Habitats

The lysobacters live in soil and fresh water and appear to be wide spread and in many places are rather abundant. They have been isolated from soils in the Netherlands (Veldkamp, 1955), Canada (Christensen and Cook, 1978; Katznelson et al., 1964; Peterson et al., 1966), the United States (Ensign and Wolfe, 1965), and

Scotland (Daft et al., 1975). In Scotland, they have been found in agricultural soils and sand dunes where the pH was neutral to slightly alkaline (pH 8.8) and not below pH 6. Population densities of up to 500 plaque-forming-units (PFU) per cm³ were observed. This may seem very low, but the isolation method was designed only to detect organisms that lyse cyanobacteria (forming plaques in the cyanobacterial lawns), which may not be the case with all lysobacters. Also, the counts would be much reduced if most of the lysobacters are attached to particles. In soil, the lysobacters probably subsist by degrading various biomacromolecules and micro-organisms other than cyanobacteria. In fact, lysobacters are known to decompose nematodes and different kinds of bacteria, as already mentioned. So, while their ecological niche is not really identified, the enzymatic equipment and lytic capabilities of the lysobacters suggest that they preferentially live in places rich in (recalcitrant) organic matter and microbial life.

Much more is known about the freshwater habitats of the lysobacters because there strains exist that can lyse living and healthy cyanobacteria and for this reason aroused much interest (see reviews by Stewart and Daft, 1976, 1977). The bacteria were found in fish ponds in Israel (Shilo, 1967; Shilo, 1970), in sewage plants in the United

States (Stewart and Brown, 1969, 1971) and Scotland (Daft et al., 1975), and in lakes, reservoirs, and rivers in Great Britain (Daft et al., 1973, 1975). This, of course, does not mean that those lytic strains are the only lysobacters living in fresh water, as lysobacters were also isolated from that source by other techniques, and the ability of these strains to lyse cyanobacteria was never specifically demonstrated (in Canada: Christensen and Cook, 1978; in Germany: H. Reichenbach and coworkers, unpublished observations).

In contrast to cyanobacterial viruses, the lytic lysobacters have a wide activity spectrum with respect to the cyanobacterial species attacked. Thus, strain FP-1 lysed 9 out of 11 species of unicellular and filamentous cyanobacteria whereas the green alga *Chlorella pyrenoidosa* and the chrysophyte *Prymnesium parvum* were completely resistant (Shilo, 1970). All Gram-negative bacteria tested were also lysed, but Gram-positive bacteria were not. Strain CP-15 disintegrated 21 out of 23 strains of cyanobacteria (Daft et al., 1973), and strains CP-1 to -4 among themselves lysed 29 out of 42 cyanobacteria from nine different genera (Daft and Stewart, 1971). In the latter case, there were slight differences among the four strains with respect to the spectra of cyanobacteria attacked, and also different strains of the same cyanobacterial species could vary in their sensitivity to lysis. All 16 British *Lysobacter* strains used in these studies were serologically related and may have belonged to one species (Stewart and Daft, 1976).

The population densities of lysobacters observed in British waters are usually low (Daft et al., 1975), but since lysobacters attach themselves to plankton and other particles, the counts may not reflect the true numbers. In lakes in summer and at the water surface, between 0 and 400 PFU/ml were found, and the numbers decreased rapidly with depth (to 1 m). But 94% of all samples contained lytic bacteria. At the height of cyanobacterial water blooms, 0.001 to 0.05% of all cultivatable bacteria were lytic, and in general the population densities of cyanobacteria and lytic bacteria correlated well, with a slight shift in the time of the maxima. Large differences in the cell numbers could occur in simultaneous samples taken from different sites in the same lake. This apparently was simply due to wind drift which caused the plankton to accumulate at certain places. In samples with particularly high densities of cyanobacteria, the numbers of lysobacters could drop substantially. As the lysobacters are strict aerobes, their decline in number under such conditions was explained by oxygen depletion during the night, but perhaps the bacteria only seem to disappear because there was now an increased opportunity for

attachment. In February, after 3 months of low phytoplankton density (and low temperature), the count of lytic bacteria fell to zero at the water surface, but some lysobacters still survived in the depth at the sediment-water interface. From there and from soils around the lakes, the repopulation of the water bodies may take place in spring. Another source for lytic bacteria was found in sewage works where in summer the counts in the final effluents were around 700 PFU/ml, and in the effluents from filter beds even as high as 1,300 PFU/ml. Also, in sewage plants, the numbers dropped during winter, in February to about 1% of the summer counts (Daft et al., 1975). Dense populations of lytic bacteria were found in the sand filters of a waterworks at a reservoir with blooming cyanobacteria. Up to 2,500 PFU/ml were found in the effluent, and 59,000 PFU/ml on the filter sand. The maximum in the open reservoir was 92 PFU/ml (Daft et al., 1973). No lysobacters were detected in water from underground springs (Daft et al., 1975).

While the lysobacters are able to lyse bloom-forming cyanobacteria, their low population densities make it questionable whether they really play a role in the control of natural water blooms. In field trials, at least 10^5 cells/ml were required to induce rapid lysis in cyanobacterial populations. In small bays at the edge of a reservoir, which were separated artificially from the main body and inoculated to a density of 10^6 bacteria/ml, there was clear evidence for lysis within 24 h at 13°C, and within 60 h, the *Microcystis* population was completely destroyed. In the lysing cell suspension the number of lytic bacteria rapidly declined, which again was explained by a lack of oxygen (Daft et al., 1973; 1975). In summary, it appears that cyanobacteria and lysobacters have similar growth requirements and simply coexist rather than prey upon one another. As the lysobacters can grow perfectly well as saprophytes, they may utilize material, including biomacromolecules, excreted by the cyanobacteria. In fact, they appear to interfere in a subtle way with the photosynthesis of the cyanobacteria and their excretion of dissolved organic carbon, reducing the rate of the former and stimulating the rate of the latter, and are able to rapidly assimilate excreted material, particularly certain amino acids, and to grow exclusively on it with a generation time of about 10 hrs (20°C). In a similar way they also exploit bloom-forming green algae like *Scenedesmus quadricauda*, which they cannot lyse at all (Fallowfield and Daft, 1988). Under conditions unfavorable for the cyanobacteria, the lysobacters also may lyse some of them, but they probably have little to do with the cyclic break down of water blooms in nature.

Isolation

Two properties of the lysobacters may be used for their enrichment: their efficient hydrolytic exoenzymes and their gliding motility. As both attributes are also found with other organisms, the enrichment techniques are not entirely specific.

Christensen and Cook (1978) recommend enriching soil samples with chitin, ground mushrooms, or *Arthrobacter* cells, and then leaving them for at least one month. After this period, the soil is suspended in water and appropriate dilutions are spread on yeast agar.

Yeast Agar

Baker's yeast	0.5%
Agar	1.5%

Adjust to pH 7.2 and autoclave.

After incubation, colonies arise that are surrounded by lysis zones, and their number increases substantially during the enrichment phase. Two types are usually observed: 1) pink-colored (*Lysobacter antibioticus*) and 2) cream-colored (*L. enzymogenes*). Rarely, also, an off-white gummy colony may appear (*L. gummosus*). On subcultivation, most of the cream colonies produce two colony variants: 1) dirty-white mucoid, and 2) yellowish nonmucoid. When water samples from lakes and rivers are used, yellow-brown colonies are obtained (*L. brunescens*).

As all lysobacters appear to degrade chitin (Christensen, 1989), one also could try to isolate them on chitin agar as described by Veldkamp (1955). He used 1% of finely powdered chitin suspended in a medium containing 0.1% K_2HPO_4 , 0.1% $MgSO_4$, and 2% agar. He purified the chitin from shrimp shells by a very cumbersome procedure, so a simpler method is given here as well as two chitin media, which are used in our laboratory with excellent results in enriching for cytophagans and myxobacteria.

Preparation of the Chitin Stock Suspension (Modified from Hsu and Lockwood, 1975)

Finely divided commercial chitin (e.g., from Fluka or Sigma) is suspended in concentrated (32%) HCl. For 40 g of chitin, approximately 400 ml of HCl is required, but sometimes more HCl (600–800 ml) has to be used. Within about 30 min, a relatively thin, blackish colloidal solution is obtained. The hydrochloric acid solution should never stand for more than 1 h at room temperature to avoid degradation of the chitin. The solution is poured into 2 liters of ice-cold water, upon which the chitin precipitates immediately as a pure white, fluffy material. It is collected on a separating funnel under suction and extensively washed. During these manipulations the material should never become dry, because drying makes it very difficult to resuspend. The washed precipitate is dialyzed against tap water for 12 to 24 h until the pH of the water

remains above at least 4.5. Then enough distilled water is added to the chitin suspension to give a slurry which is sufficiently thin to be pipetted. The pH is adjusted to 7.2 with KOH. The exact volume is determined, and the approximate chitin content of the suspension calculated from the amount employed in the beginning. The material is distributed in convenient aliquots in bottles, autoclaved, and stored at 6°C. If the precipitated chitin appears too coarse, which may happen if the starting material was not well ground, it can be further homogenized with a blender.

Chitin agars are prepared best as overlay media, which saves chitin and gives clearer results, because the layer to be hydrolyzed is thinner and the material remains at the top of the plate, so that the bacteria have an easier access to it.

CT6 Agar

Top layer:

$MgSO_4 \cdot 7H_2O$	0.1%
K_2HPO_4	0.02%
Agar	1.5%

Adjust the pH to 7.5. After autoclaving, enough of the sterile chitin suspension is added to give a good turbidity, which should be achieved with about 0.5% chitin and not more than 30% (by volume) of the suspension. The medium is poured as a thin layer on top of the following base agar:

Base agar:

Casitone (Difco)	0.1%
Yeast extract (Difco)	0.05%
$MgSO_4 \cdot 7H_2O$	0.1%
Agar	1.2%

Adjust the pH to 7.2 and autoclave.

CT7 Agar

The top layer is as above; the base agar, however, is water (WAT) agar, which is as follows:

WAT agar:

$CaCl_2 \cdot 2H_2O$	0.1%
Agar	1.5%

Adjust the pH to 7.2 and autoclave.

In CT7 agar, chitin is the only nitrogen, carbon, and energy source besides agar, and thus the medium is more selective. But not all chitin degraders grow on it. On CT6 agar, on the other hand, chitin degradation is sometimes suppressed by the peptone, and organisms that are not chitinovorous also grow on it.

Lysobacters decompose many bacteria, living and dead, and therefore may be isolated on such substrates. Strain AL-1 was obtained from lysis zones in lawns of *Arthrobacter crystallopoietes* (Ensign and Wolfe, 1965). Aqueous soil extracts were streaked on plates of medium A and incubated at 30°C.

Medium A

A basal agar with 0.5% peptone and 1% agar was overlaid with the same medium containing 10^9 cells/ml of *Arthrobacter*.

The bacteria from the plaques that developed in the lawn were purified by plating diluted suspensions on medium B.

Medium B

Agar, 1.5%, containing 10^9 cells/ml of washed *Arthrobacter*.

Presumably the *Arthrobacter* cells were living in the isolation medium and dead in the purification medium. Strain AL-1 was also maintained on medium B (at 30°C, with weekly transfers).

Similar isolation techniques may be devised with other bacteria and in fact have been used repeatedly to obtain lysobacters that lyse cyanobacteria. Stewart and Brown (1969) and Shilo (1970) isolated their organisms from water collected from a waste stabilization pond and a fish pond with a water bloom, respectively. Both groups used the soft-agar overlay technique developed for the isolation of cyanophages, and living *Nostoc muscorum* or *Plectonema boryanum* as the indicator organisms. Shilo (1970) first enriched the lytic agent by inoculating the sample into a *Plectonema* culture. While viral plaques appear after just 2–3 days, the bacterial plaques need 5–7 days to develop, and in addition are slightly sunken into the agar. Further, the bacteria also produce lysis zones in layers of autoclaved cyanobacteria. Shilo (1970) separated her strain from the cyanobacteria by transfer to a mineral salts liquid medium with 0.2% Casitone and incubation in the dark. The overlay technique may also be used for counting the lytic bacteria. Stewart and Brown (1969) determined for strain N-5 (myxobacter 44) a ratio of 1.3 for the number of viable cells to plaque-forming units.

A slightly different method was applied by Daft and Stewart (1971) and Daft et al. (1973). The cyanobacteria were grown on a suitable mineral salts medium with 0.6% agar. On the lawns produced after 7 days at 22–25°C, 1-ml water samples from the top-most layer of lakes or other surface waters, preferentially such with a cyanobacterial water bloom, were spread and the lysobacters isolated from the lysis zones that arose in the lawns. As indicator organisms, *Nostoc ellipsoforum*, *Anabaena catenula*, *A. flos-aquae*, or *Phormidium foveolarum* were used, and *N. ellipsoforum* (strain 1453/19 Cambridge University) proved particularly sensitive to lysis. The CP strains could be maintained without loss of lytic activity on CP agar.

CP Agar

K ₂ HPO ₄	17 mg
MgCl ₂ · 6H ₂ O	49 mg
CaCl ₂ · 6H ₂ O	15 mg
NaCl	60 mg
FeCl ₃	0.3 mg
EDTA	7.4 mg

Standard trace element solution*

Casitone (Difco)	2 g
Agar	6 g
Distilled water	1 liter

The mineral part is that of ASM medium (Daft and Stewart, 1971) for the cultivation of algae (and probably dispensable for the lysobacters).

*See, for example, Drews (1974), p. 6.

Lysobacter colonies may be recognized by their spreading growth due to gliding motility, and colony morphology can thus be used as a lead to isolate the organisms. Thus, on plates designed for the isolation of myxobacteria and consisting of water agar (WAT agar) with streaks of living *Escherichia coli* that are inoculated with soil, we occasionally also observe swarming lysobacters.

The purification of *Lysobacter* strains is easy and is done either by plating of diluted cell suspensions or by making transfers from the advancing edge of swarm colonies. As swarming is much reduced or completely suppressed on rich media, the latter possibility exists only when the bacterium is grown on a lean medium like yeast agar or CY agar (see below). To avoid confluence of the arising colonies, plating is done best on a rich medium such as standard nutrient agar (Difco).

Cultivation

The lysobacters are robust, adaptable organisms, and their cultivation is no problem. They actually grow on any bacteriological standard medium. Christensen and Cook (1978) recommend the three following media:

PC Agar (Plate Count Agar, Difco)

Yeast extract	0.25%
Tryptone	0.5%
Glucose	0.1%
Agar	1.5%

CC Agar (Cook's *Cytophaga* Agar; Christensen and Cook, 1972)

Tryptone	0.2%
Agar	1.0%

SA Agar (Skim-Milk Acetate Agar; Christensen and Cook, 1972)

Skim milk powder	0.5%
Yeast extract	0.05%
Sodium acetate	0.02%
Agar	1.5%

The pH for all of these media is adjusted to about 7.0 and the medium is sterilized by autoclaving. On PC agar, the colonies remain small and compact like those of nongliding bacteria, whereas on CC and SA agar, spreading swarms are obtained. Another good medium for lysobacters, including stock cultures, is the Yeast Agar mentioned above. On this medium the organisms form thin, spreading swarms, and because no or much less ammonia is produced than on the peptone media, the cultures tend to remain viable for longer time.

SA medium may also be used as a broth for liquid cultures, but a nonturbid medium is more convenient, e.g., 1% yeast extract medium (Ensign and Wolfe, 1966). We often use PEP medium.

PEP Medium

Peptone from casein, tryptically digested	1%
MgSO ₄ · 7H ₂ O	0.1%

Adjust the pH to 7.2 and autoclave.

Other peptones can be used as well, e.g., Casitone (Difco), which is a pancreatic digest of casein, and casamino acids have also been employed successfully (Gillespie and Cook, 1965). *L. brunescens* appears not to grow well or to lyse early in pure peptone media. It could, however, be cultivated with a generation time of 4 h at 20–22°C in tryptone-starch medium.

Tryptone-Starch Medium (von Tigerstrom and Stelmaschuk, 1987b)

Tryptone	0.8%
Yeast extract	0.2%
Starch	0.3%
MgCl ₂	0.02%

A fully defined medium for *L. enzymogenes* strain AL-1 was developed by Ensign and is mentioned in Tan et al. (1974):

Defined Liquid Medium (for Strain AL-1)

Aspartic acid	0.2%
K ₂ HPO ₄ · 3H ₂ O	0.34% (0.03 M)
(NH ₄) ₂ SO ₄	0.1%
MgSO ₄ · 7H ₂ O	0.01%
Tap water	1%
Glucose	0.5%

Adjust to pH 7.0 and autoclave.

Although lysobacters tolerate relatively high pH values and can grow above pH 10 (Christensen and Cook, 1978), their optimum is between pH 7 and 9. While all appear to grow at 30°C, their temperature optimum is some-

times lower, and cultivation at 25°C or even 22°C may give better results. The organisms are strict aerobes, and liquid cultures have to be shaken.

The generation times are typically around 2.5 h (2.3 h for *L. enzymogenes* strain 495 in 0.8% yeast extract broth at 22°C; von Tigerstrom and Stelmaschuk, 1989; and 2.6 h for strain myxobacter 44 in a mineral salts medium with 0.2% starch and 0.25% peptone, 30°C; Stewart and Brown, 1971. Much longer generation times of 10.7 and 12.6 h are reported for growth under quasi-natural conditions in nutrient-poor culture filtrates from cyanobacteria and green algae, respectively (strain CP-1, 20°C; Fallowfield and Daft, 1988). A maximum cell yield of 2.5 g/l (dry weight) was obtained with strain 495 in condensed fish solubles with 2% glucose (Wah-On et al., 1980).

Large-scale fermentations with lysobacters have been performed for the production of the antibiotic myxin, and of an enzyme complex capable of lysing living yeast cells. While apparently nothing has been published about the industrial process developed by Hoffmann-La Roche (Nutley, NJ) for the manufacture of myxin with strain "*Sorangium*" 3C, some data on 10-liter fermentations are given in a Canadian patent (Can. Pat. 784,213; 30 April 1968). The fermentation was performed in the following medium: Tryptone, 0.1%; glucose, 0.1%; K₂HPO₄, 0.1%; MgSO₄, 0.02%; CaCl₂, 0.01%; and FeCl₃, 0.001%; at pH 7.5 and 25°C. The aeration rate was 0.1 liter air per liter medium and min; the stirring rate, 300 rpm; the harvest time, 20 h with a 2% (v/v) inoculum, and 12 h with a 10% inoculum.

Production of yeast-lytic enzymes by "*Cytophaga*" NCIB 9497 was studied at up to a 900–1 liter scale (Asenjo et al., 1981). The medium consisted of 1% yeast extract and 1% glucose and permitted a maximum growth rate (μ_{\max}) of 0.36 h⁻¹. The inoculum size was 3.8%, the initial pH 7.2, and the temperature 26°C. The aeration rate was set at 0.2 liter air per liter medium and min, and the impeller tip speed between 1.21 and 1.57 m·sec⁻¹ (around 100 rpm). It appeared that a relatively low level of dissolved oxygen around 20–30% was favorable, particularly in the beginning. Polypropylene glycol 2000 was added as an antifoam agent and was well tolerated at 2 ml/l but not higher. Still, after 24 h, the broth began to foam heavily. Harvest was at 30 h with a good yield of active enzyme, part of which was set free only by cell lysis at the end of the fermentation. Early cell lysis may be a serious problem. Obviously it is essential to start with young, vigorous seed cultures, e.g., from freeze-dried material.

Preservation

Stock cultures may be kept on yeast agar at room temperature (21°C) and should be transferred every 1 to 2 weeks. With stock cultures on peptone media, production of toxic levels of ammonia can be a problem. Storage of cultures in the cold is not recommended. In one reported case, all cells were dead after 3 weeks at 5°C (Asenjo et al., 1981). It seems understandable that the lytic enzymes produced by lysobacters also destabilize resting cultures.

Lysobacters survive freezing very well, either at -80°C or in liquid nitrogen. Cells from young plate cultures are suspended in PEP medium, or young shake cultures in the same medium are taken, and 1-ml samples are frozen without further precautions. The preserved cultures are reactivated by immersing them in tap water for a quick thawing and transferring the content as soon as it is liquefied. The longest storage period we have tested so far was 13 years at -80°C, which was reliably tolerated by all strains.

Lysobacters also can be lyophilized in skim milk by the standard procedure. It is reported that reactivated freeze-dried cultures may show a slightly different colony morphology and reduced bacteriolytic and proteolytic activity (Christensen, 1989). We dry the organisms with good results at room temperature, which may be less harmful to them. A few drops of a cell suspension in sterile skim milk are applied to a plug of lyophilized skim milk in an ampule. The wetted plug is then dried in vacuo, the ampule filled with nitrogen gas, and sealed.

Characterization

Morphologically, the various lysobacter species resemble one another closely (Christensen and Cook, 1978; Christensen, 1989). The cells are slender cylinders with rounded ends, and, at least in young healthy cultures, are rather regular in shape (Figs. 1 and 2). They typically measure 0.3–0.6 × 2–6 µm, but much longer threads, up to 70 µm, are usually also present. Those filaments obviously are incompletely divided cells and cell chains. A mixed population of short and long cells is very characteristic for the lysobacters and distinguishes them at once from any myxobacterium. To avert confusion, it should be mentioned that the morphological description given by Veldkamp (1955) of his chitinolytic strain does not fit the present NCIB 8501 strain, which indeed is a typical lysobacter. Instead, Veldkamp has given the morphology and cyclic-shape change of *Flexibacter filiformis*, which also is strongly chitinolytic.

Electron micrographs of thin sections show a typical Gram-negative cell wall, large mesosome-like structures in the center or at the poles, and granules interpreted as poly-β-hydroxybutyrate and polyphosphate. On the surface there may be ruthenium-red-positive material, presumably slime (Shilo, 1970; Stewart and Brown, 1971; Stewart and Daft, 1977); in other cases no such material was seen (“myxobacter” AL-1: Pate and Ordal, 1967). True rhabdosomes, i.e., the contracted tails of a defective phage (Reichenbach, 1967), were found in cell lysates of “*Sorangium*” 495 (Pate et al., 1967).

In contact with an interface, the lysobacters may move by gliding. The movements usually are rather slow but observable under the microscope. An average speed of 1 µm per min (30°C) has been reported (Veldkamp, 1955). When suspended in liquid the cells are nonmotile.

On lean media like CC, SA, and yeast agar, most lysobacters produce thin, filmlike swarms with little flamelike extensions at the edge (Figs. 3 and 4). Only *L. gummosus* appears not to spread on any medium, and its gummy colonies always show an entire edge. In general, the spreading of lysobacter swarms is not too fast, and it may take 2–3 weeks before they cover the entire plate. The swarm sheet itself may be somewhat slimy, but otherwise it is rather unstructured and smooth. This distinguishes the lysobacter swarms from myxobacterial swarms, which almost always are morphologically differentiated with radial veins, concentric ridges, and oscillating waves or ripples, and which in addition may etch themselves deeply into the agar surface (degenerate strains may produce homogeneous, slimy swarms). On rich media like PC agar, the colonies tend to remain compact, small, with a smooth convex surface and an entire edge. Those colonies often are highly mucoid. Enough slime may be produced to drop from the colony into the lid of the inverted dish (Ensign and Wolfe, 1965). As briefly mentioned, *L. enzymogenes* produces two different colonies, one dirty-white and mucoid, the other yellowish and nonmucoid. While both colony types are always obtained when starting from white colonies, the yellow ones yield only the yellow type. Physiologically and biochemically, the two organisms are identical (Christensen and Cook, 1978). Often, small, colorless crystals are seen within the colonies (Fig. 3e). In the case of *L. gummosus*, the colonies are of a rubbery consistency.

The color of colonies of *Lysobacter* may be off-white; cream; pale to deep yellow, sometimes with a greenish hue; pinkish; salmon; or orange-brown, depending on the species and on the medium. The chemical nature of those pigments is not known. The published absorption spectra of crude extracts show maxima or shoulders at

455, 482, and 516 nm (*n*-hexane) for salmon-colored strain FP-1; 448, 466, and 470 nm (ethanol) for three yellow "myxobacters" (Stewart and Brown, 1971); and 424, 442, and 464 nm (in methanol) for the yellow strains CP-1 and CP-15 (Daft and Stewart, 1971; Daft et al., 1973). While those spectra suggest a polyene chromophore, perhaps a carotenoid, they may be spectra of a mixture of pigments and thus cannot be reliably interpreted. Many strains produce a water-soluble, dark-brown, probably melanoid pigment, which is particularly prominent in old cultures and on media containing amino acids or peptones. Color reactions of phenolic compounds indicate the presence of a mono- and diphenol oxidase (Stewart and Brown, 1971). Deep-red crystals of myxin may appear within the colonies of *L. antibioticus*. Also, many cultures give off an unpleasant *Pseudomonas*- or pyridine-like odor.

In agitated liquid media, the lysobacters grow as homogeneous cell suspensions. When gently rotated, those cultures appear silky. Depending on the medium, liquid cultures may become somewhat viscous, and those of *L. gummosus* virtually solid.

Relatively little has been published about the composition of the lysobacter cell. A typical Gram-negative peptidoglycan was demonstrated in *L. enzymogenes* strain AL-1, with *meso*-diaminopimelic acid and D-alanine cross-bridges (Harcke et al., 1975). The inner and outer membrane could be separated starting from osmotically shocked cells. The outer membrane had a density of 1.30 g·cm⁻³ (CsCl), the inner one of 1.23 g·cm⁻³ (Hartmann et al., 1977). Ubiquinone Q-8 is the only respiratory quinone of *L. antibioticus* and *L. enzymogenes* (M. D. Collins, personal communication). This allows one to quickly distinguish lysobacters from myxobacteria as well as from organisms of the *Cytophaga* group (including high GC strains of *Taxobacter*) which all contain menaquinones exclusively. The ribosomes of "myxobacter" 495 (*L. enzymogenes*) were difficult to isolate because tightly bound nucleases and proteases were attached to them and could not be removed by the usual methods (Sendecki et al., 1971). Otherwise, lysobacter ribosomes have the typical prokaryotic composition. The rRNA has the same base ratio as that of *E. coli* (GC/AU = 1.20). The presence of poly- β -hydroxybutyrate in the lytic "myxobacters" was substantiated by its conversion into crotonic acid (Stewart and Brown, 1971). The compound accumulates in the course of cultivation, with a maximum on the third day. Capnoids, a new type of sulfonolipids found in bacteria of the *Cytophaga* group (Godchaux and Leadbetter, 1983), and multicopy single-stranded DNA common in myxobacteria

(Dhundale et al., 1985), are both absent in lysobacters. The lysobacter DNA has a high GC content of 65–71 mol% (Christensen and Cook, 1978; Daft and Stewart, 1971; Mitchell et al., 1969; Shilo, 1970; Stewart and Brown, 1971).

A number of metabolic enzymes have been studied in *L. enzymogenes* strain AL-1 (Guntermann et al., 1975; Hartmann et al., 1977). In the cytoplasm there is an α - and a β -glucosidase, a β -galactosidase, and an isocitrate dehydrogenase; on the cytoplasmic membrane, a succinate dehydrogenase; and bound to the outer membrane, an alkaline phosphatase and a *N*-acetyl glucosaminidase. The activities of those enzymes change during the cell cycle. Two distinct patterns were noted, one for the five hydrolases, the other for the two dehydrogenases. In the case of the α -glucosidase, the activity increase was shown to be due to *de novo* enzyme synthesis. While β -glucosidase and β -galactosidase are constitutive, α -glucosidase is inducible by maltose. In a study on the phylogenetic implications of the isozyme pattern of 3-deoxy-D-arabinoheptulosonate 7-phosphate synthase (important for the synthesis of aromatic amino acids) in superfamily B (to which *Lysobacter* belongs according to 16S rRNA data), *L. enzymogenes* was found to possess only one enzyme variant, the one that is sensitive to feedback inhibition by tryptophan and, unique for *Lysobacter*, ultrasensitive to chorismate (Ahmad et al., 1986). This pattern is shared only by group V pseudomonads, which fits its classification based on 16S rRNA studies. In addition, the lysobacters produce a host of exoenzymes. As some of those are of a more general interest and have found applications, they will be discussed under "Practical Aspects," this chapter.

For a large number of strains, comparative physiological and biochemical tests were performed and used for the differentiation of species (Christensen, 1989; Christensen and Cook, 1978). The strains studied for their ability to destroy cyanobacteria were not characterized in the same scheme as those able to destroy other bacteria, so that the following generalizations may not always apply to them.

The lysobacters are aerobic organisms, although many strains appear to grow best at a reduced oxygen level (10% O₂). In the oxidation-fermentation (OF) test with glucose, practically all strains show oxidative growth but many also show fermentative growth. Growth of the lytic freshwater organisms stops immediately when the culture is flooded with N₂ gas; no growth is obtained in paraffin-sealed tubes, and the generation time increases to 9 h (30°C) when the oxygen tension is reduced to 20% of the normal atmospheric pressure (Daft et al., 1975; Stewart and Brown, 1971). Catalase and oxidase

are positive, but the catalase reaction is very sensitive to the culture conditions and sometimes is very weak or even absent (H. Reichenbach, unpublished observations).

The pH range is 4.5 to over 10, the optimum between 7 and 9. There is almost always a remarkable tolerance to alkaline conditions. Even the freshwater strains usually grow well at pH 9 (Stewart and Brown, 1971; Daft et al., 1975). The ability to grow at an acid pH varies with the different strains; many do not grow below pH 6. During growth on peptones, the pH may rise substantially due to ammonia production.

The temperature optimum is usually around 30°C, even for the freshwater organisms, but it varies substantially from isolate to isolate. It may be as low as 25°C or as high as 40°C. A few strains can grow at 2°C and at 50°C, but the limits often are 4 and 40°C.

The salt tolerance is usually limited to 1% NaCl or less, and no strain was found to grow in the presence of 3% NaCl.

The lysobacters are chemoorganotrophs. For many strains, NO_3^- , NH_4^+ , glutamate, or asparagine serve as the sole nitrogen source whereas urea appears to be utilized only by a few strains. Some organisms, however, are more fastidious. Several of the strains that lyse cyanobacteria do not grow on inorganic nitrogen (Daft et al., 1973; Shilo, 1970), while others do (Stewart and Brown, 1971). All lysobacters grow on peptone as the only organic substrate, but the type and concentration of the peptone may be critical. Casitone (Difco) seems to be suitable in all cases, but strain FP-1 has a low optimum of 0.2% for Casitone and does not grow at 0.5%. The same strain also does not accept yeast extract, tryptone, or casamino acids, and does not grow on nutrient broth or nutrient agar (Shilo, 1970). In general, peptides appear to be the preferred carbon and energy source, and monosaccharides may only be used slowly (von Tigerstrom and Stelmaschuk, 1987b).

Glucose is probably utilized by all strains. Growth may take place on a wide spectrum of carbohydrates, e.g., in one case on: glycerol, mannitol, arabinose (weak), glucose, galactose, fructose (weak), mannose, lactose, sucrose, raffinose, and rhamnose (Veldkamp, 1955). Acid is produced from glucose and from several other sugars in a varying pattern that may be useful for the differentiation of species. Many strains grow on citrate as the sole carbon source.

All strains are strongly proteolytic as can be seen, e.g., by cultivation on skim milk agar. They liquefy gelatin, peptonize milk, and produce α -, β -, or γ -type hemolysis on sheep blood agar, including strain AL-1, which originally was reported to be negative for hemolysis (Ensign and Wolfe, 1965). Almost all lysobacters hydro-

lyze chitin. Veldkamp (1955) observed *N*-acetylglucosamine, glucosamine, acetic acid, and NH_4^+ as products. Several of the isolates that decompose cyanobacteria did not attack chitin (the failure was perhaps due to the method used; Stewart and Brown, 1969; Daft et al., 1975), while others do (Stewart and Brown, 1971). Crystalline cellulose (filter paper) is not decomposed, but many strains degrade carboxymethyl cellulose, and at least some strains can even grow on it as the only organic substrate (Stewart and Brown, 1971). While agar is not liquefied or softened, gelase fields (uncolored areas) may appear upon flooding with iodine solution (Shilo, 1970). Starch, pectate, and alginate may or may not be decomposed. Many strains produce lipases that cleave Tweens.

Ammonia is produced from proteins and peptones. Nitrate is only rarely reduced to nitrite. Some strains generate H_2S . The indole, methyl red, and Voges-Proskauer tests are always negative, and the phosphatase test is always positive.

Sodium dodecyl sulfate usually diminishes growth at 0.01% and completely inhibits it at 0.1%. All lysobacters appear to be sensitive to polymyxin B, although the result may vary somewhat with the way the test is done (Christensen and Cook, 1978; Shilo, 1970; Stewart and Brown, 1971). This is a valuable distinguishing characteristic in so far as most *Cytophaga*-like bacteria are resistant to polymyxin B (Mitchell et al., 1969). All strains of *L. brunescens* as well as the freshwater lysobacters (Shilo, 1970; Stewart and Brown, 1971) also are rather sensitive to actinomycin D (around 2 $\mu\text{g}/\text{ml}$), which is in contrast to most Gram-negative bacteria but in accordance with the behavior of most other gliding bacteria (Dworkin, 1969). All *L. brunescens* strains are inhibited by chloramphenicol, penicillin G, and usually also streptomycin, but most other lysobacters are not. Strain FP-1 was also resistant to erythromycin and tetracycline, but inhibited by kanamycin and neomycin (Shilo, 1970). The strains of Stewart and Brown (1971) and of Daft et al. (1975) were sensitive to all these and several more antibiotics.

As already mentioned, the lysobacters are able to kill and disintegrate many living and healthy microorganisms, such as both Gram-positive and Gram-negative bacteria, including actinomycetes and cyanobacteria; filamentous fungi; algae; and even nematodes. Gram-negative strains are usually less readily killed and lysed than Gram-positive ones. The first signs of lysis may be observed within minutes after the culture broth has been added to a suspension of sensitive bacteria (Gillespie and Cook, 1965). The technique by which the lysobacters destroy cyanobacteria is particularly well documented

(Daft and Stewart, 1971, 1973; Daft et al., 1973, 1975; Shilo, 1970; Stewart and Brown, 1970). They use two different mechanisms: 1) One strain, strain N-5 (myxobacter 44) attacks the cyanobacteria with free exoenzymes (Stewart and Brown, 1969, 1970, 1971). The first assault seems to be on the cell wall with lysozyme-like enzymes, but later the whole cell with the exception of the membranes is digested. Heterocysts and akinetes are more resistant but finally also destroyed. Only their walls remain. 2) All other strains need to be in contact with the cyanobacteria before they can lyse them (Daft and Stewart, 1973; Shilo, 1970). Since neither culture supernatants nor cell extracts are sufficient to disintegrate cyanobacteria on solid or in liquid media, enzymes bound to the surface of the lysobacter cell are probably involved. It appears that the lysobacters move actively toward their prey, perhaps attracted by the oxygen produced by photosynthesizing cells. They attach themselves with one cell pole often close to the cross-septa of the filaments, and then become fixed perpendicularly on the surface of the target cells. No special organelle for attachment is recognizable. The need for contact explains why lysis does not take place in shaken cultures. In unshaken liquid cultures, the lysobacters are found fixed to the cyanobacteria within 20 min after mixing. A single lysobacter cell may lyse a *Nostoc* cell within 20 min. It then moves on and attacks another cell in the filament. There is no specific order in which the cells along a filament are assaulted. When a lysobacter culture of a sufficiently high cell density is added to a cyanobacterial population, lysis may be complete within 1 to 3 h. The time required depends, of course, on environmental factors, notably oxygen and temperature. Thus, in a well-aerated culture at 26°C, *Nostoc ellipsosporum* is completely destroyed within 60 min. On ultrathin sections in the electron microscope, it can be seen that the first structure to disappear is the peptidoglycan layer. The cell contents are then gradually broken down, and only the cell membranes, lipid droplets adhering to them and, if present, the gas vacuoles remain. The latter rise to the surface where they can be collected. The membranes often coil up, looking in cross-sections like scrolls. Protoplasts may be released from the filaments. If there is an outer sheath, it also may disintegrate. In the case of *Oscillatoria redekei*, amorphous material disappears from the sheath and a fibrous layer is left. Heterocysts initially resist lysis but eventually also disintegrate, either under the impact of the bacterial enzymes or by autolytic processes started after the cells are released from the filaments. In infected cyanobacterial cultures, the chlorophyll *a* content and the nitrogenase activity go down concomitantly with lysis, so that

either parameters can be used to measure its progress (Daft et al., 1973).

Tan et al. 1974 have devised a method to establish synchronized cultures of myxobacter AL-1: Cells of different sizes, equivalent to different stages of the growth cycle, were separated by centrifugation in a sucrose density gradient. As already mentioned, in this way, changes of enzyme activities during growth could be determined.

Taxonomy and Identification

The first step in the identification procedure is to make sure that an isolate belongs to the genus *Lysobacter*. An organism qualifies as a lysobacter if it is a chemoorganotrophic, aerobic, unicellular, gliding, Gram-negative bacterium with a GC content of 65 to 71 mol%. Those characteristics are, however, shared by the myxobacteria and by certain organisms of the *Cytophaga* group (such as *Taxeobacter*). Some myxobacteria have a very similar cell shape (for instance, *Polyangium*, *Sorangium*, and *Chondromyces*) but the populations never show the variation in cell length typical for lysobacters. The morphology and structure of myxobacterial swarms is usually completely different, myxobacteria produce fruiting bodies and myxospores, and they contain menaquinones instead of ubiquinones as respiratory quinones. The organisms of the *Cytophaga* group, as far as they are gliding, may form very similar soft, slimy swarm colonies, but their cells usually look much different, they often contain flexirubin-type pigments and always menaquinones. The colonies of most *Cytophaga*-like bacteria are more-or-less yellow to orange, often brightly colored, particularly on peptone agar, and turn red if covered with 20% KOH (flexirubin reaction), which is never observed with lysobacter strains. Unfortunately, *Taxeobacter*, the only genus that in its GC content comes close to *Lysobacter*, is red. It has a similar cell shape to *Lysobacter*, but its cells are much stouter and tend to arrange themselves side-by-side in a palisade like fashion. Also, *Taxeobacter* lacks the unpleasant smell of *Lysobacter*.

Presently, four *Lysobacter* species are recognized. Their differential characteristics are listed in Table 1. The separation of the species rests entirely on physiological and biochemical data and is based on phenotypic analysis of a large number of strains (Christensen and Cook, 1978). However, the relatively wide GC range of the strains of two species (65–70 mol% in *L. enzymogenes* and 66–69 mol% in *L. antibioticus*) and the substantial differences in the temperature maxima of strains of *L. brunescens* (37–50°C) suggest that more than one taxon may

Table 1. Characteristics distinguishing the four species of *Lysobacter*.

Character	<i>L. enzymogenes</i> ^a	<i>L. antibioticus</i>	<i>L. brunescens</i>	<i>L. gummosus</i>
Colony morphology	Sheetlike, soft slimy	Sheetlike, soft slimy	Thin, filmlike	Compact, gummy
Colony color	Cream to greenish-yellow	Pink to greenish-yellow	Yellow to brown	Yellowish-gray
Viscosity of broth cultures	+	+	–	+++
Urea as sole N-source	V	–	–	+
Citrate as sole C-source	+	+	+	–
Acid from cellobiose	+	+	–	+
Acid from sucrose	+	+	–	+
Acid from lactose	+	V	–	+
Hydrolysis of carboxymethyl cellulose	+	+	–	+
Hydrolysis of pectate	+	–	+	+
Hydrolysis of starch	V	–	+	–
Hemolysis (sheep blood)	α, β, or γ	β or α	γ or –	α
Sensitive to chloramphenicol	V	–	+	–
Sensitive to actinomycin D	V	–	+	V
GC content, T _m (mol%)	65–70	66–69	67	66

^bFormerly "*myxobacter*" or "Sorangium" 495. ^cFormerly "Sorangium" 3C. Adapted from Christensen (1989) and Christensen and Cook (1978).

be hidden among the strains presently allocated to one species. First attempts to subdivide one of the species have been made (*L. enzymogenes* subsp. *enzymogenes* and subsp. *cookii*; Christensen and Cook, 1978), but before that can reasonably be done, the methods of molecular taxonomy, notably DNA-DNA hybridization, need to be used. It seems doubtful whether the occurrence of myxin can be used as a characteristic of the species *L. antibioticus*, because production of an antibiotic usually is strain- and not species-specific.

As there is a free exchange of organisms between soil and fresh water, the habitats given in Table 1 for the various species should not be taken as absolute. In fact, the "freshwater" lysobacters attacking cyanobacteria have also been found in soil (Daft et al., 1975), and we have isolated myxin-producing lysobacters from freshwater (H. Reichenbach, unpublished observations).

Two more species not shown in Table 1 also have been proposed *L. lactamgenus* (Ono et al., 1984) was studied because of its new cephem antibiotics, the cephabacins. While several characteristics of the strain are in accordance with a lysobacter, it differs substantially in its extremely high GC content (76 mol%, T_m) and in its inability to produce acid from any sugar. *L. albus* (Nozaki et al., 1987) synthesizes the novel antibiotic lactivicin. The description of this isolate is very preliminary and lacks essential data, e.g., on gliding motility and GC content. Acceptance of the new species will require that the strains be made freely accessible to others in the field.

Practical Aspects

The spectacular lytic capabilities of the lysobacters suggest that they may play an important role in the control of microbial populations in nature, although their population densities appear never to become high enough to cause a breakdown of a cyanobacterial water bloom (Daft et al., 1975). Still, it may be possible to eliminate blooming organisms in a limited area, or pathogenic or otherwise undesirable bacteria in sewage plants, like the filamentous organisms responsible for the bulking of sludge, by introducing lysobacter strains with strong, lytic enzymes. The potential is probably limited by the requirement for cell-to-cell contact as a prerequisite for lysis, which would restrict any application to nonagitated environments, such as trickling filters or dense, floating mats of the target organisms.

The ability of lysobacters to synthesize new secondary metabolites is of particular importance. The following antibiotics have been isolated from lysobacters (and *Lysobacter*-like organisms): the phenazine-*N*-oxide, myxin (Peterson et al., 1966; Weigle and Leimgruber, 1967); two cyclic decapeptides, myxosidin A and B (Clapin and Whitaker, 1976, 1978 Monahan and Whitaker, 1976); the quinoline compound, G 1499–2 (Evans et al., 1978); new cephem antibiotics, the cephabacins (Harada et al., 1984; Ono et al., 1984); the acyltetramic acids, catacandin A and B (Meyers et al., 1985); a dicyclic dipeptide with lactam-like properties, lactivicin (Harada et al., 1986, 1988 Nozaki et al., 1987, 1989); and a

dibasic macrocyclic peptide lactone, lysobactin (Bonner et al., 1988; O'Sullivan et al., 1988; Tymiak et al., 1989).

Of those antibiotics, myxin has been produced industrially by Hoffmann-La Roche in Nutley for some time. It was applied in the form of a copper chelate called cuprimyxin and sold under the trade name Unitrop®. In contrast to free myxin, the chelate is very stable and practically insoluble. In contact with animal tissue, myxin is gradually released, so that the complex guarantees a sustained activity. Cuprimyxin was applied topically, mainly against skin infections including dermatophytes, and its use was restricted to veterinary medicine. The antibiotic is produced by strains of *L. antibioticus*, which was originally named "*Sorangium*" 3C (in the chemical literature, it is often further mislabelled as "*Sporangium*"). Myxin acts on DNA. There exists a voluminous literature on the various aspects of myxin, which can, however, not be reviewed here (see, e.g., on the chemistry: Sigg and Toth, 1967; Weigele and Leimgruber, 1967; Weigele et al., 1971; on the mechanism of action: Behki and Lesley, 1972; Lesley and Behki, 1967; on the biological activity and application: Grunberg et al., 1967; Maestrone and Brandt, 1980; Maestrone and Mitrovic, 1974; Maestrone et al., 1972; McDonald et al., 1980; Snyder and Imhoff, 1975).

The main reason why the lysobacters initially were noticed was their rich stock of exoenzymes. Several of those enzymes have a potential for an application in research or industry. One of the *Lysobacter* proteases has been studied in great detail for theoretical reasons and is one of the best-understood enzymes. Again, the literature on this topic is by far too extensive to be reviewed here comprehensively (see below).

Strain NCIB 8501 (if the present strain is really identical with the one first described, see above) was the first lysobacter to be studied for its exoenzymes, a chitinase complex (Veldkamp, 1955). The products of the enzymatic activity are *N*-acetylglucosamine, acetate, and ammonia, but not glucose. While chitin decomposition is a common feature of the lysobacters, it appears that so far no other study has been performed on the subject. An extracellular enzyme with both β -1,4-glucanase and chitosanase activity was purified from *L. enzymogenes* strain AL-1 (Hedges and Wolfe, 1974). It does not attack chitin. Enzymes of this type are probably responsible for the often-observed hydrolysis of carboxymethyl cellulose. They could also be useful for the study of the structure of fungal cell walls. Strain "Cytophaga" L1 (= NCIB 9497) was patented for its impressive combination of fast-working hydrolytic exoenzymes (Brit. Pat. 1,048,887, 23 November 1966). The enzyme complex includes chitinase, laminarinase, lipase, elastase, kerati-

nase, and other proteolytic activity and may be useful for the decomposition of fungal mycelia from fermentations. Using the same strain, a process was later worked out for the degradation of living yeast cells (Andrews and Asenjo, 1984; Asenjo, 1980; Asenjo and Dunnill, 1981; Asenjo et al., 1981; Hunter and Asenjo, 1987a, 1987b). The yeast lytic enzymes are produced constitutively and consist of β -(1-6)-glucanase, mannanase, and high protease activities. The breakdown of the yeast cells is connected mainly with the protease and the glucanase activities, which have to act in sequence because a specific protease must remove the mannoprotein layer in the outer cell wall before the glucanase can become active. As the glucanase is repressed if more than 0.8 g of glucose is present per liter of medium, a 20-fold-higher enzyme yield is obtained in continuous cultures with optimal dilution rates compared with batch cultures. The lysobacter glucanase appears not to adsorb to the yeast glucan, attacks the fibrillar and the amorphous glucan fractions equally well, and shows no inhibition by its hydrolysis products. If crude enzyme preparations are applied in higher concentrations, the rate of lysis may decline. This may be due to competitive inhibition by carbohydrates present in the enzyme solution. The lysobacter enzyme mixture solubilizes the yeast cells almost completely and thus appears particularly useful for the production of yeast extract and of animal feed. A two-step model has been proposed to describe the kinetics of the process of lysis. Also, the separation of the enzyme complex from the culture broth and its application in an immobilized form has been studied. It appears, however, that the free enzyme is more promising for technical purposes.

Two alkaline phosphatases were demonstrated in *L. enzymogenes* strain 495 (von Tigerstrom, 1983; 1984; von Tigerstrom and Stelmaschuk, 1986, 1987a). The appearance of both activities is repressed by inorganic phosphate. One of those enzymes is excreted into the medium, has a molecular weight of about 25 kDa, and does not contain a metal ion, which is rather unusual for a bacterial phosphatase. As the enzyme is easy to recover and purify, it might be a useful tool in nucleic acid research. The other enzyme appears to be bound to the outer membrane, has a molecular weight of about 69 kDa, and seems to be composed of at least two subunits. It is a metal enzyme probably containing Zn^{2+} , hydrolyzes a wide variety of 5', 3', and 2'-ribose and -deoxyribose nucleotides, as well as sugar phosphates, and shows a remarkably high specific activity. A corresponding cell-bound phosphatase was also found in the three other *Lyso-bacter* species, and all four enzymes are immunologically related among themselves but

completely different from cell-associated phosphatases from other gliding bacteria. The extracellular and the cell-bound phosphatase also differ in their amino acid composition.

The same strain produces two extracellular endonucleases (von Tigerstrom, 1980, 1981). One is a nonspecific nuclease (22–28 kDa) preferentially cleaving double-stranded DNA and, with reduced efficiency, single-stranded DNA and RNA, but not poly(A) and poly(C). It produces large oligonucleotides with 5'-phosphate groups. The synthesis of this enzyme is inhibited by RNA in the medium. The second enzyme is an RNase (46–47 kDa) that also cleaves poly(A) and poly(C) but not double- and single-stranded DNA. It appears to have no base specificity. The enzyme is unusual in that it generates short oligonucleotides with 5'-phosphate ends (instead of the more common 3'-phosphate groups). The production of the RNase is inhibited by phosphate in the medium. During its purification, a contaminating enzyme was discovered that degraded the dialysis bags. The extracellular enzymes of strain 495 are obtained with good yields in tryptone (0.4%) broth at 25°C (von Tigerstrom, 1983). While the production of nuclease, RNase, and phosphatase is inhibited by Mg^{2+} and by Mn^{2+} above 0.1 and 0.01 mM, respectively, that of protease is stimulated by Mg^{2+} and neutral to Mn^{2+} . The ions appear to interact specifically with the synthesis of the enzymes and not with their release from the cells.

Other hydrolases excreted by lysobacters are: endoamylases found in all four species (von Tigerstrom and Stelmaschuk, 1987b), which seems surprising because the characterization of the lysobacter species excludes starch hydrolysis in almost all strains of three species (see Table 1); the paradox may be a result of the test conditions. The enzyme of *L. brunescens*, the most potent organism, has a molecular weight of 47–49 kDa and also decomposes amylopectin, amylose, and glycogen, but not dextran. The enzyme probably has no commercial interest because of its enzymatic properties and low yield. Further, all species produce two extracellular lipolytic esterases (von Tigerstrom and Stelmaschuk, 1989). One is excreted into the medium and is inducible by olive oil. As it is synthesized only after exponential growth, it appears to be under catabolite repression. The other enzyme is associated with the outer membrane and is constitutive. The two esterases differ in their substrate specificity. Both are very active on Tween 20, but only the free enzyme is able to attack olive oil. In addition, there is a third, cytoplasmic esterase which, in contrast to the extracellular enzymes, is very active on tributyrin. Finally, there is a periplasmic β -lactamase.

The most fascinating *Lysobacter* enzymes are their proteases. Two proteases were isolated from the culture supernatant of *L. enzymogenes* strain ("Sorangium" or "myxobacter") 495; one of them α -lytic protease, became a very important enzyme for scientific reasons. The strain was originally noted for its ability to rapidly lyse a wide spectrum of bacteria (Gillespie and Cook, 1965) and nematodes (Katznelson et al., 1964). Soon it was realized that the lytic activity was due to at least two different proteases, α - and β -lytic proteases (Whitaker, 1965), and procedures were worked out to produce and purify those enzymes (Whitaker et al., 1965a; Whitaker, 1967a). Later it was found that there are at least two more proteases in the culture broth.

A major research effort has been made to characterize the α -lytic protease. This enzyme is an alkaline serine protease (for a summary of the early work see: Whitaker, 1970) that aroused great interest because it was the first bacterial serine protease with the same amino acid sequence in its active center, Gly-Asp-Ser-Gly-Gly, as the mammalian pancreatic serine proteases (Olson et al., 1970; Whitaker et al., 1966; Whitaker and Roy, 1967), and not Thr-Ser-Met as in most other bacterial serine proteases. This suggested a common ancestor for both enzymes and invited studies on the evolution of protein structure and function. The similarity to porcine pancreatic elastase is particularly notable, a similarity which also extends to substrate specificity and kinetic properties (Kaplan and Whitaker, 1969; Kaplan et al., 1970). While the homology in the amino acid sequence is only high in certain critical regions (overall homology 18%), long sections appear conserved in the three-dimensional structure as revealed by high-resolution X-ray analyses and molecular models (55% topological equivalence). There is an even higher correspondence with *Streptomyces griseus* proteases A and B, with 35% and 36% sequence homology and 80% topological equivalence (e.g., Brayer et al., 1979; Fujinaga et al., 1985; McLachlan and Shotton, 1971). The α -lytic protease (EC 3.4.21.12; 19.8 kDa) consists of 198 amino acids and contains three disulfide bridges. It cleaves polypeptides at the carbonyl side of short neutral aliphatic amino acids, preferentially alanine (Kaplan and Whitaker, 1969). It also attacks bacterial peptidoglycans, mainly at the cross-linkages (Tsai et al., 1965). Like other serine proteases, α -lytic protease has several subsites (in this case, six) for substrate binding, with different amino acid specificities (Bauer et al., 1981). This explains why the enzyme prefers long substrate molecules over short ones. While the pH optimum for catalytic activity is reached at pH 8, substrate binding is independent of pH

between pH 5 and 10.5 (Kaplan and Whitaker, 1969; Paterson and Whitaker, 1969). The enzyme shows a high stability unparalleled in any other protease (Kaplan et al., 1970), which appears to arise from a high structural rigidity (Fujinaga et al., 1985). As with other serine proteases, a strong H-isotope effect is observed: the catalytic rate drops to one-third in $^2\text{H}_2\text{O}$ (Hunkapiller et al., 1973). The discovery that α -lytic protease contains but one histidine (His) residue (Jurášek and Whitaker, 1967) proved particularly momentous for the elucidation of the catalytic mechanism of serine proteases, for the other enzymes all contain more than one His. This finding at once excluded a requirement of several His residues for the catalytic process, as was postulated before. The histidine in α -lytic protease is homologous with the His-57 in α -chymotrypsin and is part of the catalytic triad, Asp-102/His-57/Ser-195 (the adopted numbering is that of α -chymotrypsin). By the use of a His auxotrophic mutant, ^{13}C and ^{15}N could substantially be enriched in His-57 (Westler et al., 1982), which allowed refined NMR studies of the dissociation behavior and hydrogen bonding in the active center (Bachovkin, 1986; Bachovkin et al., 1981; Hunkapiller et al., 1973). Another approach was the use of peptide-boronic acid inhibitors forming rather stable enzyme-substrate complexes, which can be analyzed as models of the otherwise-not-accessible transition state (Bone et al., 1987; 1989). Those studies provided deep insights into the mechanism of catalysis and substrate specificity. The gene of α -lytic protease (the *pro* gene) has also been cloned in *Escherichia coli* (Epstein and Wensink, 1988; Silen et al., 1988). At the amino end of the protease domain, the gene has an open reading frame that extends 198 (or 199: the two articles do not completely agree in the details) amino acid codons upstream and represents a very large prepro sequence. The latter consists of a typical bacterial pre (or signal) peptide of 24 (or 33) amino acids ending with a Ala-Leu-Ala-Ala cleavage site, followed by a pro region of 174 (or 166) amino acids, i.e., more than twice the size of other known bacterial propeptides. The high sequence homology observed between α -lytic protease and proteases A and B of *Streptomyces griseus* continues for 49 amino acids into the pro region (21% and 38% homology, respectively), and then falls suddenly to a low value of 7% and 3%. This suggests that the *Lysobacter* pro region is a composite of two parts, perhaps of different origin and with different functions. In fact the amino acid sequence around the cleavage site of the signal peptide shows a unique homology to a trypsin inhibitor of maize, and it was speculated that this part of the peptide may block the protease activity, while the conservative part

may serve an identical function as the (much shorter) propeptides of proteinases A and B, namely, arranging the correct folding of the protease domain (Epstein and Wensink, 1988). The *Lysobacter* ribosomal binding site (AGGAG) is homologous to known *E. coli* binding sites. When the *Lysobacter* gene is fused with an inducible *E. coli* promoter and signal sequence (e.g., *pho A*), α -lytic protease is expressed in *E. coli* and (probably unspecifically) exported into the medium (Silen and Agard, 1989; Silen et al., 1989). Deletion of the pro region results in inactive enzyme, which is immunologically and electrophoretically indistinguishable from α -lytic protease, but presumably improperly folded. Site-specific mutation of the Ser-195 in the catalytic pocket leads to the production of a double-sized inactive protease molecule, which suggests that the removal of the propeptide is an autocatalytic process. Surprisingly, the activation (not the production) of α -lytic protease proved temperature sensitive and did not take place above 30°C. If the pro region and the protease domain were cloned separately with independently inducible *E. coli* promoters, active enzyme was obtained when both were induced concomitantly, in spite of the fact that in this case, the two peptide were not covalently connected. Obviously, the propeptide functions as a chaperonin-like, though specific, folding template. It appears that α -lytic protease is produced exclusively by strain 495.

Much less is known about the β -lytic protease, a second protease from strain 495. The enzyme is a nonserine protease and resembles mammalian carboxypeptidase and particularly the bacterial neutral proteases (Oza, 1973). Its specificity is quite distinct from that of the pancreatopeptidases. It cleaves very selectively at the carbonyl side of neutral amino acids. Thus, only the B chain of (denatured) insulin is cleaved, and that between glycine-23 and phenylalanine-24 and, much more slowly, between valine-18 and cysteine-19 (Whitaker et al., 1965b). A free α -amino group or a free terminal carboxyl next to the cleavage site is not accepted, but an amido group on the carboxyl already eliminates the blocking effect of the latter. The β -enzyme is more active than the α -enzyme on bacterial peptidoglycan rapidly hydrolyzing the muramic-acid alanine bond (Tsai et al., 1965). The β -lytic protease (19 kDa) appears to be composed of 177 amino acids and to contain two disulfide bridges and one atom of zinc (Jurášek and Whitaker, 1967). The zinc can be removed and restored again with reconstitution of enzyme activity (Whitaker, 1967b). While the apoenzyme is no longer proteolytic (Oza, 1973), the cell-wall-lytic activity was still observed (Whitaker and Roy, 1967). But conceivably the protease was simply restored by

a contamination of the peptidoglycan with zinc. The pH optimum of β -lytic protease is 6.5 (Oza, 1973). The proteases of strain 495 can be produced with good yields (4–4.5 g of α - and 2 g of β -enzyme from 100 liters) on casamino acid/glucose media (Whitaker, 1967a). Also, production on media with condensed fish solubles, a by-product of the salmon canneries, seems feasible (Wah-On et al., 1980).

Finally, the proteases of *L. enzymogenes* strain ("myxobacter") AL-1 (ATCC 27796) should briefly be mentioned. The organism was isolated because it lysed cells and cell walls of *Arthrobacter crystallopoietes*, and enzymes with that property were of much interest at that time for studies on the cell wall structure of bacteria (Ensign and Wolfe, 1965, 1966). In fact, one of the AL-1 enzymes was soon successfully applied for that purpose (for a review, see Ghuysen, 1968). The enzyme is particularly useful because it cleaves the bond between muramic acid and L-alanine, making it possible to isolate the pure polysaccharide backbones of peptidoglycan. The enzyme could thus be used to demonstrate a shortening of the polysaccharide chain length during the rod-to-sphere conversion of *Arthrobacter* (Krulwich et al., 1967). At first, only the enzyme just mentioned, AL-1 protease or, later, AL-1 protease I, was recognized and characterized (Ensign and Wolfe, 1966; Jackson and Wolfe, 1968; Jackson and Matsueda, 1970). The enzyme can be produced by fermentation in 1% yeast extract medium at 30°C for 36 h, and is recovered from the culture supernatant with a yield of 350 mg of pure enzyme from 100 liters. The AL-1 protease I (13.5 kDa) is an alkaline endopeptidase with a sharp pH optimum at 9.0. The molecule consists of 136 amino acids, with Ser, Asp, Gly, Thr, and Ala accounting for more than 50% of the residues. It contains one disulfide bridge, and does not contain a hexose molecule, as was previously suggested. The enzyme is spherical, compact, and very stable. Within minutes, it completely lyses whole cells of many Gram-positive and some Gram-negative bacteria, as well as purified peptidoglycan (Ensign and Wolfe, 1965). It cleaves about 30% of the bonds in casein and albumin, and 15% in gelatin. In the B chain of insulin only the bonds between Ala and Leu, Gly and Phe, and Val and Cys are attacked. Thus it appears that a hydrophobic residue is required at the cleavage site, but the exact specificity is not yet known. In peptidoglycan, besides the connection of the peptide side chain to the polysaccharide backbone, only the bonds between terminal D-Ala and the pentaglycine or L-Ala bridges, and bonds within the pentaglycine bridge are cleaved. The enzyme therefore became a useful tool for the elucidation of the structure of bacterial cell walls (e.g., Ghuysen, 1968; Jarvis and

Strominger, 1967; Katz and Strominger, 1967; Tipper, 1969).

Also, the second protease from strain AL-1, AL-1 protease II (17 kDa), is a small, stable, alkaline endopeptidase, but it does not attack bacterial cell walls (Wingard et al., 1972). It is obtained from the culture supernatant with a yield of 10% of protease I. The enzyme is very unusual in two respects: it readily crystallizes from the column fractions, and it cleaves exclusively at the amino side of lysine. It does not remove terminal lysine residues. The enzyme consists of 157 amino acids, 50% of which are Asp, Ala, Thr, and Gly, and has a broad pH optimum between 8.5 and 9.0.

A third unusual protease from AL-1 is called endoproteinase Lys-C. This enzyme has a high although not absolute specificity for peptide and ester bonds at the carboxyl end of lysine (information leaflet Boehringer Mannheim, Biochemica-Dienst no. 42, April 1980), so that it can be used for sequencing proteins and for peptide mapping (Au et al., 1989; Boileau et al., 1982; Hofsteenge et al., 1983; Jekel et al., 1983; Jolles et al., 1983). The enzyme (30 kDa unreduced, 33 kDa reduced) is an alkaline serine protease, is very stable even in the presence of 0.1% sodium dodecylsulfate or 5 M urea, and is commercially available from Boehringer Mannheim (Mannheim, Germany).

The Genus *Moraxella*

JOHN P. HAYS

The *Moraxella* genus currently contains at least 14 different species, including *M. catarrhalis*, *M. bovis*, *M. lacunata*, *M. osloensis*, *M. nonliquefaciens*, *M. atlantae*, *M. lincolnii*, *M. ovis*, *M. caviae*, *M. canis*, *M. equi*, *M. cuniculi*, *M. caprae* and *M. boeveyi*, which colonize both humans and animals. The genus is under constant revision, with recent taxonomic restructuring placing the bacterial species formerly known as *Moraxella phenylpyruvica* in the genus *Psychrobacter* as *Psychrobacter phenylpyruvica* and *Moraxella urethralis* in the *Oligella* genus as *Oligella urethralis* (Fig. 1).

Common characteristics of the *Moraxella* genus include a lack of colony pigmentation; Gram-negative staining coccobacillus and bacillus morphology (except *M. catarrhalis*, which exhibits a coccoid morphology; Fig. 2), with a tendency to resist decolorization; positive with oxidase reagent and tetra- and dimethyl-*p*-phenylenediamine; and a G+C content of 40–47.5 mol%. Optimum growth conditions are achieved on blood agar plates under aerobic conditions at a temperature of approximately 33–37°C. *Moraxella lacunata* colonies form dark haloes on chocolate agar, most often with pitting of the agar (a phenomenon only occasionally observed for other *Moraxella* spp.). The addition of bile salts and sodium desoxycholate to the growth medium tends to stimulate *M. atlantae* but inhibits the growth of *M. lacunata* and *M. nonliquefaciens*. Combined genetic transformation and nutritional assays for the identification of *Moraxella nonliquefaciens* have been reported (Juni et al., 1984). In general, however, distinguishing between the different *Moraxella* species tends to be difficult (Table 1), not least because of the asaccharolytic nature of the genus, though some publications have indicated that 16S rRNA sequence polymorphisms may be a useful adjunct to biochemical testing (Enright et al., 1994a; Pettersson et al., 1998a; Harmsen et al., 2001). When combined, biochemical and 16S rRNA sequence data do not tend to warrant a distinction of the *Moraxella* genus into two distinct subgenera as suggested by Bovre (1984).

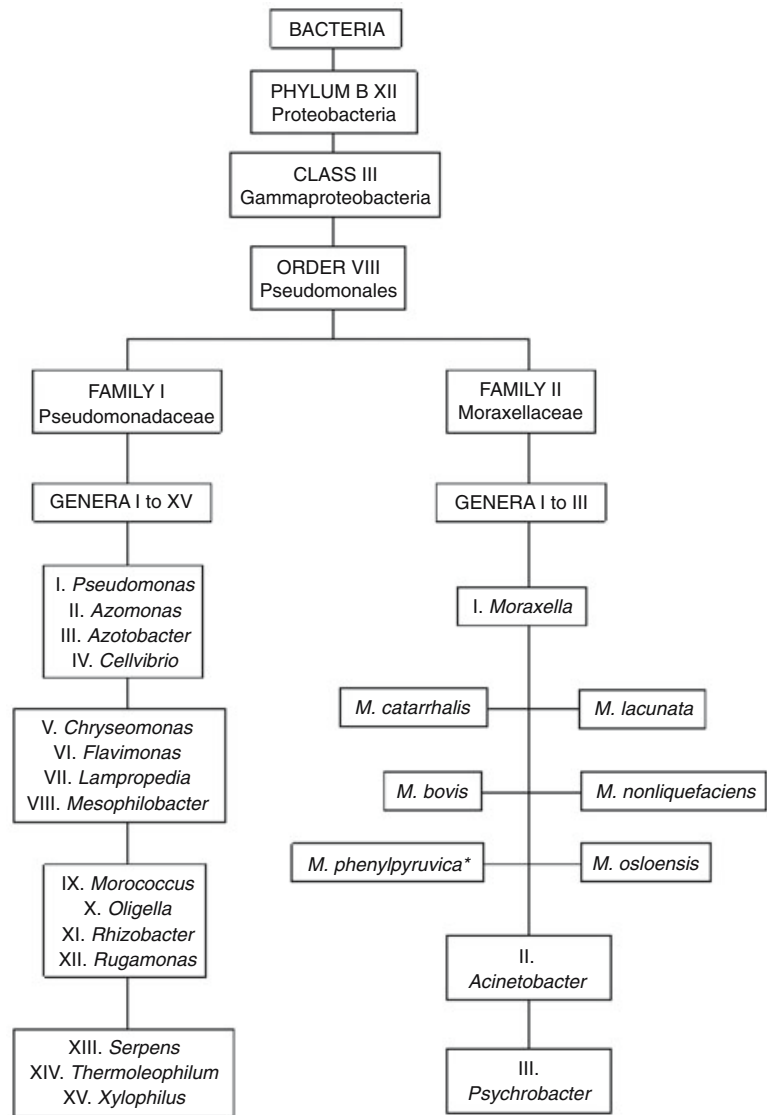

Moraxella lacunata, *M. osloensis*, *M. nonliquefaciens*, *M. atlantae* and *M. lincolnii* are commensals of human epithelia that are infrequently associated with human disease. Though only infrequently associated with human disease (*M. catarrhalis* excluded), the range of diseases caused by *Moraxella* spp. in humans is somewhat broad and includes: 1) ocular infections, e.g., conjunctivitis and endophthalmitis; 2) respiratory infections, e.g., “pneumococcal pneumoniae” and chronic bronchitis; and 3) systemic infections, e.g., bacteremia, septic arthritis, acute thyroiditis, neonatal meningitis, central venous catheter infection and bone and joint infection (*panarthritis ossale et articulare*).

Several *Moraxella* species are associated with animals, including *M. canis* (cats and dogs), *M. ovis* (sheep), *M. equi* (horses), *M. caprae* and *M. boeveyi* (goats), *M. caviae* (guinea pigs) and *M. cuniculi* (rabbits). Like their human counterparts, these animal-associated *Moraxella* spp. are infrequently associated with facilitating disease (*M. bovis* excluded), though *Moraxella* infections related to chronic cholera-like lesions in birds, and keratoconjunctivitis in mule deer and moose, have been described (Emerson, 1983; Dubay, 2000). *Moraxella bovis* is actually an important veterinary pathogen, a situation that mirrors the importance of *M. catarrhalis* as the single most important human pathogen within human commensal *Moraxella* species.

The majority of *Moraxella* spp. is susceptible to penicillin-derived antibiotics, including cephalosporins, tetracyclines, quinolones and aminoglycosides. This contrasts with *M. catarrhalis*, where an alarming increase in the number of penicillin resistant isolates has been observed in the last 30 years (now approximating 90–95% of all isolations). This distinction in antibiotic sensitivity is most probably related to the fact that *M. catarrhalis* produces β -lactamases, a phenomenon apparently rare in other *Moraxella* spp. (though at least one publication has indicated otherwise with respect to *M. nonliquefaciens*; Eliasson et al., 1992).

The exceptional importance of *M. bovis* and *M. catarrhalis* in veterinary and human infection

within the *Moraxella* genus means that a more detailed discussion of these pathogens is warranted.

Moraxella bovis

Moraxella bovis is the most common cause of infectious bovine keratoconjunctivitis (IBK), an epidemic and highly contagious disease causing temporary or even permanent blindness, predominantly in calves (Henson and Grumbles, 1960). The bacterium is thought to comprise part of the normal bacterial flora of bovines, colonizing the ocular and nasal epithelia (Moore and

^aFor truest microscopic morphology, perform Gram staining with a sample from enrichment broth culture incubated for 2 h at 35°C.

^b*Brucella* species may be misidentified as *Psychrobacter (Moraxella) phenylpyruvicius* in some commercial identification systems.

^cMay be difficult to demonstrate.

^dTest performed by directly inoculating surface of SBA in a manner that will produce a uniform lawn of growth, immediately placing a 10-U penicillin disc on the agar surface, and incubating in room atmosphere at 35°C for 18–24 h. Any strain with a zone of inhibited growth around the penicillin disc is interpreted as susceptible for identification purposes.

^eSome strains, particularly those in Europe, may be β-lactamase negative and therefore penicillin susceptible.

Rutter, 1989; Kodjo et al., 1993) with spread of the organism within herds possibly occurring via face flies (Diptera: Muscidae; Arends et al., 1984; Glass and Gerhardt, 1984). Some evidence suggests that not all *M. bovis* infections result in overt disease (Powe et al., 1992).

Isolation and Identification

Several selective methods for the isolation of *M. bovis* from animal derived specimens have been described, including the use of Tween 80 agar (Mattinson and Cox, 1982), and medium MB (but not medium Mn-B; Juni et al., 1987; Juni et al., 1988), as well as growth on conventional media (e.g., blood agar, GC agar base with 1% IsoVitaleX; Pugh et al., 1966). Further, Webber (1982) indicated that the incorporation of 2.5 micrograms/ml of cloxacillin into 5% bovine blood agar may provide an inexpensive culture medium for the primary isolation of *M. bovis* from bovine lacrimal and nasal secretions (Webber et al., 1982). Both antibody techniques (Nayar and Saunders, 1973; Turfrey, 1985; Wan-nemuehler et al., 1989) and molecular methods (e.g., multilocus enzyme electrophoresis and hybridization with pilin-specific DNA probes) have also been used to distinguish *M. bovis* from other *Moraxella* spp. (Tonjum et al., 1992).

Interstrain variability and typing of *M. bovis* isolates has been performed using a series of techniques, including 1) serology (slide agglutination [SA], enzyme-linked immunosorbent assay [ELISA], and tandem-crossed immunoelectrophoresis [TCIE]; Gil-Turnes and de Araujo, 1982; Gil-Turnes and Albuquerque, 1984; Moore and Rutter, 1987; Moore and Lepper, 1991); 2) a combination of genetic, outer membrane protein (OMP) and lipopolysaccharide (LPS) analyses (Prieto et al., 1999); and 3) random amplification of polymorphic DNA (RAPD; Conceicao et al., 2004). Plasmid identification has also been suggested as an additional useful method for *M. bovis* strain identification since a range of plasmids (up to 45 kb in size) has been identified within the species (McDonald and Pugh, 1986; Wilt et al., 1989).

Pathogenicity

Moraxella bovis exhibits several pathogenic traits, including the expression of adhesins, leukotoxin, phosphoamidase, phosphatase, hyaluronidase, lipases, etc. (Frank and Gerber, 1981; Gil-Turnes and Aleixo, 1991). However, of particular importance with respect to virulence, is the presence or absence of pili (fimbriae; Jayappa and Lehr, 1986; Lepper and Power, 1988b; Ruehl et al., 1988) and the expression of

a hemolysin or cytolysin (Kagonyera et al., 1989).

Pili (fimbriae) have been shown to mediate adherence of *M. bovis* to bovine corneal cells in vitro (Annuar and Wilcox, 1985), and nonpiliated strains are nonvirulent during experimental corneal infection of laboratory mice and cattle (Jayappa and Lehr, 1986). Interestingly, single isolates possess the capacity to make more than one type of pilin (Marrs et al., 1988). For example, strain Epp 63 (the most intensively studied) expresses alpha (I) and beta (Q) fimbrial variants, which possess approximately 70% sequence identity. Moreover, the beta (Q) variant is significantly more virulent than the alpha (I) or nonpiliated variants (Ruehl et al., 1988; Ruehl et al., 1993). Further, phase variable expression of the pilin genes per se (i.e., pilated versus nonpilated and vice versa) has also been demonstrated (Bovre and Froholm, 1972).

Hemolysin is a calcium-dependent, repeats-in-toxin (RTX)-related toxin of 94–110 kDa molecular mass (Gray et al., 1995; Billson et al., 2000), which is secreted by most pathogenic *M. bovis* cells. The hemolysin creates cellular pores that ultimately inflict damage to bovine erythrocytes (e.g., by making them swell and leak internal solutes; Clinkenbeard and Thiessen, 1991) as well as bovine neutrophils (facilitating cytotoxicity; Hoiem-Dalen et al., 1990). The *M. bovis* hemolysin per se is encoded by the *mbxA* gene, part of a typical RTX operon comprising four genes arranged *mbxCABD* (5'-3'). Flanking this operon lies putative transposases (5') and *tolC*-like genes (3'), with nonhemolytic strains apparently lacking the operon (Angelos et al., 2003). The hemolysin may be inactivated by heat, trypsin, formalin, or lyophilization (Sandhu and White, 1977; Ostle and Rosenbusch, 1984), and in broth cultures, reaches a maximum concentration approximately 4.5 h after inoculation (late logarithmic phase). Cattle with a history of infectious bovine keratoconjunctivitis are found to have high antihemolysin antibody titers in their blood (Ostle and Rosenbusch, 1985), and vaccination with hemolytic cell-free extracts has been shown to protect against IBK (Billson et al., 1994).

Treatment and Vaccination

The use of antibiotics is a viable option in treating *M. bovis*-mediated keratoconjunctivitis (Pugh and McDonald, 1977a; George et al., 1984), with most antibiotics showing low minimum inhibitory concentrations (MICs) against *M. bovis* including ampicillin, ceftiofur, tilmicosin, tylosin, erythromycin, oxytetracycline and gentamicin (Shryock et al., 1998). In particular, long-acting oxytetracycline has been proven to

reduce corneal ulceration (Smith and George, 1985) and lower the incidence of keratoconjunctivitis (George and Smith, 1985). However, differences in antibiotic sensitivity between individual isolates have been determined (Gil-Turnes and Albuquerque, 1984).

Vaccination is also under investigation as a means of controlling *M. bovis* infection. However, different *M. bovis* isolates produce serologically different types of pili (Sandhu et al., 1974), and a single isolate may express different pili forms at different times, which means that protective immunity is generally only conferred by antiserum raised against homologous isolates (Pugh et al., 1977b; Lepper, 1988a, Moore and Rutter, 1989). Moreover, there are indications that switching of pilin type within individual isolates (to a different pilus serotype) may occur after vaccination with a single homologous pilus serotype (Lepper et al., 1995). The use of a polyvalent subunit pilus vaccine in protecting cattle against IBK has been proposed and used with varying degrees of success (Lepper et al., 1992; Lepper et al., 1995). Other *M. bovis* vaccines have used pooled bacterin from various non-hemolytic strains, or ribosomes, and have had mixed success in preventing IBK in calves (Pugh et al., 1981; Pugh et al., 1982). The use of adjuvants (e.g., diphtheria-tetanus-toxoids and pertussis vaccine [DPT]) has been shown to be useful in promoting the development of a serological response to pili-related vaccines (Pugh et al., 1984).

Moraxella catarrhalis

The bacterial species known as *Moraxella catarrhalis* (also referred to as "*Branhamella catarrhalis*" or "*Moraxella [Branhamella] catarrhalis*") was originally thought to be a common human commensal bacterium with little pathogenic potential, a characteristic currently shared by most other species within the *Moraxella* genus. However, evidence collected over the last 30 years has proven the clinical relevance of this organism in facilitating disease in both adults and children. The main question now remaining is the bacterium/host mechanism(s) allowing the organism to switch from being a harmless commensal to a facilitator of pathogenic disease.

Taxonomy

Moraxella catarrhalis has undergone several name changes since its first discovery in 1896 (Frosch and Kolle, 1896). Originally entitled *Micrococcus catarrhalis*, the organism became more familiar as *Neisseria catarrhalis* in the 1950s, largely due to its Gram-negative, diplococoid morphology and rapid oxidase positive

reaction (characteristics associated with *Neisseria* species). In 1963 however, Berger showed that this genus may actually contain two distinct species (*Neisseria cinerea* and *Neisseria catarrhalis*), which could be separated by their biochemical ability to reduce nitrate and nitrite and to utilize tributyrin (Berger, 1963). With the introduction of DNA technology, further phylogenetic studies indicated a lack of chromosomal DNA homology, between the "true" *Neisseria* spp. and *N. catarrhalis*, so much so, that in 1970 the species was renamed "*Branhamella catarrhalis*" and relocated to the new genus of *Branhamella* to honor the famous microbiologist Sarah E. Branham who had previously conducted research on *Neisseria* (Catlin, 1970). Fourteen years later, Bove suggested that *B. catarrhalis* be renamed "*Moraxella (Branhamella) catarrhalis*" and be re-assigned to the genus *Moraxella*, not least because of the distinct physiological and genetic relatedness between *Branhamella catarrhalis* and members of the *Moraxella* genus (Bove, 1984). In 1991, Catlin suggested the formation of a new family (the Branhamaceae), which would accommodate both *Branhamella* and *Moraxella* genera and take into account the differences in morphology (cocci versus rods) and pathogenicity (important mucosal pathogens versus rare causes of disease) (Catlin, 1991). However, this suggestion has not been adopted by taxonomists, not least because 16S ribosomal RNA sequence analysis and genetic hybridization studies tend to favor the current classification of *M. catarrhalis* (Enright et al., 1994b; Pettersson et al., 1998b). Currently, the *Moraxella* genus contains both rod-shaped and coccoid bacteria exhibiting similar genetic relatedness, though taxonomic revision of the genus is a continuing process. Indeed, growing evidence suggests that the current *M. catarrhalis* genus may actually represent two different subspecies or even distinct species per se (Bootsma et al., 2000a; Verduin et al., 2000).

Isolation and Identification

Optimum growth conditions for *M. catarrhalis* include a temperature of 35–37°C in an atmosphere containing 3–7% CO₂, though the organism is also capable of growing at a larger range of temperatures (20–42°C) and in ambient air. Pure cultures of *M. catarrhalis* may be grown on standard laboratory media including Mueller Hinton agar, Columbia blood agar, and brain heart infusion or tryptic soy digest broths, though the addition of supplements, e.g., boiled blood plus vitamin and amino acid enrichment (chocolate agar), may result in an enhancement of growth (Doern and Morse, 1980). *Moraxella catarrhalis* does not grow on Modified Thayer-

Martin (MTM) medium. A defined medium for *M. catarrhalis* culture has been described by Juni et al. (Juni et al., 1986), however the growth of *M. catarrhalis* from clinical specimens may be complicated by the presence of the normal bacterial flora, and in particular, the presence of nonpathogenic *Neisseria*. For this reason, selective agars may best be used for the isolation of *M. catarrhalis* from clinical specimens such as sputum etc. Several types of selective media have been described for *M. catarrhalis* with a common feature being the inclusion of trimethoprim, vancomycin, and an antifungal agent, with the further addition of acetazolamide (a synthetic sulfonamide) having been reported to enhance recovery (Vaneechoutte et al., 1988). Of interest, *M. catarrhalis* isolated on modified in New York City (MNYC) medium containing antibiotics selective for pathogenic *Neisseria* may possess a greater virulence potential than isolates that do not grow on this medium (El-Ahmer et al., 2003). For long-term storage (several years) at -80°C , STGG (skimmed milk, tryptone, glucose, glycerol) medium has been reported to yield encouraging results (Kaijalainen et al., 2004).

Moraxella catarrhalis colonies tend to be large, gray or nonpigmented, smooth, opaque and convex in nature and may be readily pushed intact over the surface of agar using a sterile loop. In a typical Gram film, the organism appears as a Gram-negative diplococcus with flattened sides, though physical appearance by itself is not enough to separate the species from related contaminating *Neisseria* spp. The identification of *M. catarrhalis* to the species level involves biochemical testing with the production of oxidase, expression of a DNase, lack of acid production from glucose, sucrose, lactose, maltose and fructose, reduction of nitrate and nitrite, and the hydrolysis of tributyrin being important, though none of the tests by themselves are 100% specific or sensitive (Catlin, 1990). The use of DNA technology, and in particular the polymerase chain reaction (PCR) technique, has allowed the direct detection of *M. catarrhalis* from clinical isolates (middle ear effusions, nasopharyngeal secretions etc.) without the prior need for culture. The validity of PCR detection has been proven in animal models (Post et al., 1996; Aul et al., 1998). Indeed, results show a superior sensitivity for PCR (down to six or seven genome equivalents, over more traditional culturing methods; Post et al., 1996). Recent research has also shown that PCR may be used to follow quantitative changes in *M. catarrhalis* numbers in nasopharyngeal secretions in "real-time," perhaps offering a sensitive and reliable means of following disease progression and treatment regimens in the future (Greiner et al., 2003). However, perhaps the most useful aspect of PCR, with regard to clinical

diagnosis, is the ability of multiplex PCR protocols to detect several pathogens in a single reaction mix, including the acute otitis media (AOM) bacterial pathogens *M. catarrhalis*, *Hemophilus influenzae* and *Streptococcus pneumoniae*. Such multiplex PCRs have already been validated in animal models (Bakaletz et al., 1998) and have been shown to be a reliable diagnostic tool allowing screening of middle ear effusions for several pathogens (including *Alloiococcus otitidis*) within a single reaction tube and within a single working day (Hendolin et al., 1999).

Bacterial Typing and Epidemiology

Traditionally, typing of *M. catarrhalis* isolates (for determining the relatedness of isolates during nosocomial outbreaks etc.), has been performed using a series of nonmolecular techniques, including susceptibility to human serum mediated bacteriolysis, trypsin sensitivity and agglutination profiles against human group O erythrocytes (Soto-Hernandez et al., 1989), isoelectric focusing of β -lactamase proteins (Nash et al., 1991), serological typing of lipopolysaccharide (Van Hare et al., 1987; Vaneechoutte et al., 1990), electrophoretic profiling of outer membrane proteins (Bartos and Murphy, 1988; Murphy, 1989a), autoaggregation properties (Janicka et al., 2002), as well as a few other miscellaneous techniques (Denamur et al., 1991; Peiris and Heald, 1992; Peiris et al., 1994). However, advances in DNA technology have allowed comparative whole genomic testing to be performed. The simplest of these techniques involves the use of restriction endonuclease enzymes to specifically digest the genomic DNA of isolates, followed by gel electrophoresis to separate the individual fragments (Patterson et al., 1989; Kawakami et al., 1994; Christensen et al., 1995). *Hae*III, *Hind*III, *Pst*I, *Cla*I and *Spe*I are particularly useful enzymes in this respect. Particularly successful and popular at present is the use of macrorestriction analysis (pulsed field gel electrophoresis or PFGE), which has been used to type *M. catarrhalis* isolates, particularly in the nosocomial situation (Martinez et al., 1999; Vu-Thien et al., 1999; Yano et al., 2000; Hays et al., 2003b; Masaki et al., 2003; Fig. 3). Interestingly, the use of several genomic techniques, including strain-specific DNA probes (Beaulieu et al., 1991; Walker et al., 1998), automated ribotyping, and amplification fragment length polymorphism (AFLP) analysis (Bootsma et al., 2000a; Verduin et al., 2000) have all indicated the division of *M. catarrhalis* isolates into two distinct phylogenetic clusters (possibly subspecies). Further, *M. catarrhalis* isolates expressing various virulence traits (complement resistance and increased adherence to epithelial cells) have

Fig. 3. Dendrogram showing pulsed field gel electrophoresis (PFGE) patterns obtained from *M. catarrhalis* isolates isolated from children admitted to or attending a pediatric intensive care unit in the Netherlands. Letters E and M represent isolates with similar PFGE patterns. (From Hays et al., 2003a, with permission.)

been found to be statistically associated with one of these two clusters (Bootsma et al., 2000a; Verduin et al., 2000). Such genomic typing studies have also shown the genetically diverse nature of *M. catarrhalis* isolates, with successive clonal expansions (often linked to geographic location) apparently occurring (Enright and McKenzie, 1997; Martinez et al., 1999). Interspecies horizontal transfer of genes between *M. catarrhalis* and other species that inhabit the same niche also appears possible (Bootsma et al., 2000b; Luna et al., 2000).

Associated Diseases

Although once considered a harmless commensal, *M. catarrhalis* is now recognized as an important pathogen of humans and associated with upper and lower respiratory tract infections in both children and adults (Karalus and Campagnari, 2000). In particular, *M. catarrhalis* tends to be associated with upper respiratory tract infections (including acute otitis media and sinusitis) in children, but lower respiratory tract infections in adults (usually with pre-existing pulmonary disease). Occasionally, the bacterium is reported as the causative agent of certain nonrespiratory tract associated infections, including bacteremia (Doern et al., 1981; Domingo et al., 1995; Ioannidis et al., 1995; Abuhammour et al., 1999), endocarditis (Neumayer et al., 1999; Stefanou et al., 2000), conjunctivitis and keratitis (Macasai et al., 1988; Abbott, 1992a; Weiss et al., 1993), and tracheitis (Ernst and Philp, 1987). Less frequently, the organism has been associated with meningitis (Daoud et al., 1996), ventriculitis (Cooke et al., 1990; Rotta et al., 1995), ophthalmia neonatorum (Paul et al., 2000), acute mastoiditis (Leskinen and Jero, 2003), and septic arthritis (Abbott and Nageswaran, 1992b; Oliveri et al., 2004). Interestingly, many reports have indicated the seasonal incidence of *M. catarrhalis* infection, with the winter and spring months showing the greatest rates of isolation (Pollard et al., 1986; Sarubbi et al., 1990; Wood et al., 1996). Moreover, this seasonality is not a prominent feature of respiratory infection caused by other associated bacteria, e.g., *S. pneumoniae* or *H. influenzae* (DiGiovanni et al., 1987; Davies and Maesen, 1988; Kilpi et al., 2001), and there is some speculation that seasonal viral respiratory tract infection (e.g., respiratory syncytial virus [Alligood and Kenny, 1989; El-Ahmer et al., 2003] but not adenoviruses [Bakaletz et al., 1995]) may be a predisposing factor in the seasonality of *M. catarrhalis* infection. Another theory involves bacterial-bacterial competition involving *Corynebacterium* spp., which form part of the normal human throat microflora (Rikitomi et al., 1989).

From a clinicians perspective, it is also important to note that *M. catarrhalis* may be isolated as part of a mixed population of pathogens. For example, research has indicated that isolation of *M. catarrhalis* from sputa is accompanied by the isolation of other bacterial pathogens on approximately 40–50% of occasions (the most common being *S. pneumoniae* and *H. influenzae*; Nicotra et al., 1986; Pollard et al., 1986; Hager et al., 1987). In such cases, defining the role of *M. catarrhalis* in the disease process may be clinically important, particularly with respect to antibiotic therapy, i.e. should antibiotic therapy be targeted against the co-isolated organism only, *M. catarrhalis* only, or should a broad spectrum antibacterial agent be used?

CHILDHOOD INFECTIONS

Otitis media Acute otitis media (AOM) is the most frequent infection associated with *M. catarrhalis* in children (Faden et al., 1990; Faden et al., 1991; Faden et al., 1997; Faden, 2001) and comprises inflammation of the middle ear accompanied by a liquid effusion (Klein et al., 1989; McCormick, 2002). Approximately 50% of children will have experienced at least one episode of AOM by their first birthday, with this proportion rising to 70% by 3 years of age (Teele et al., 1989a; Teele et al., 1989b; Klein, 1994; Turner et al., 2002), representing a tremendous disease burden for this age group and necessitating the widespread use of antibiotics (Cohen et al., 2000; Pichichero, 2000; Pichichero and Casey, 2002). *Moraxella catarrhalis* has been recognized as a specific pathogen associated with AOM for over 70 years (Hart, 1927), and is the third most common bacterium isolated from this condition (behind *H. influenza* and *S. pneumoniae*; Comisso et al., 2000; Gehanno et al., 2001; Patel et al., 2002). During routine visits, Faden et al. (1994a) observed that otitis media prone children were colonized on 44.4% of occasions compared to only 16.7% of occasions for otitis non-prone children, suggesting a link between increased *M. catarrhalis* colonization and the occurrence of otitis media. However, a genetic relationship between colonizing *M. catarrhalis* isolates and otitis media was not found (Hays et al., 2003b). Of note, the actual rate of *M. catarrhalis* associated AOM may be underestimated, as tympanocentesis and culturing of middle ear effusions is not routinely performed. Also, the development and use of vaccines against *H. influenza* and *S. pneumoniae* could facilitate an increase in the percentage of AOM episodes attributed to *M. catarrhalis*. The use of new PCR-based methodologies also provides evidence for the presence of *M. catarrhalis* in culture negative middle ear effusions from children suffering

chronic otitis media (Post et al., 1996). Since 1980, the number of reported *M. catarrhalis* isolations from middle ear effusions of children suffering from AOM appears to have markedly increased (now approximating 15–20%), an increase also accompanied by the appearance of β -lactamase producing strains which now account for approximately 90–95% of all isolates (Kovatch et al., 1983; Marchant et al., 1992; Patel et al., 1995; Block, 1997). There is some suggestion that *M. catarrhalis* may facilitate the spread of β -lactamase genes to other bacterial species during mixed bacterial infections (Kadry et al., 2003). It is perhaps poor consolation that the actual numbers of bacteria isolated from middle ear effusions and the severity of symptoms during AOM episodes appear to be lower when *M. catarrhalis* is isolated rather than *S. pneumoniae* or *H. influenzae* (Faden et al., 1992a). Recent recommendations for the treatment of acute otitis media have been presented by Hoberman et al. (2002).

Sinusitis Sinusitis is another very common infection in childhood, having been estimated to account for approximately 5–10% of upper respiratory tract infections within this age group (Wald et al., 1989; Wald, 1992a; Wald, 1992b; Wald, 1997; Wald, 1998). Accurate diagnosis may be difficult due to the presence of fairly nonspecific symptoms, which are often similar to allergy or upper respiratory tract viral disease (Daele, 1997). Clinically, sinusitis may be divided into two separate groups, the acute group (where symptoms persist for 10–30 days) and the subacute group (where symptoms persist for 30–120 days). In both cases, *M. catarrhalis* accounts for approximately 5–10% of bacterial infections, with *S. pneumoniae* and *H. influenzae* being more commonly isolated (Chan and Hadley, 2001; Brook, 2002; Finegold et al., 2002). There is some suggestion however, that the rate of isolation of *M. catarrhalis* may be underestimated with respect to sinusitis, as the bacterium grows poorly in environments containing reduced oxygen concentrations (Brorson et al., 1976).

Lower Respiratory Tract Infections in Children

The role of *M. catarrhalis* in the etiology of lower respiratory tract infections (LRTI) in children seems to be clear-cut. The organism has been isolated in pure culture from tracheal aspirates obtained from neonates, infants and children with pneumoniae (Haddad et al., 1986; Berg and Bartley, 1987; Boyle et al., 1991; Berner et al., 1996). Interestingly, *M. catarrhalis* appears to be increasingly isolated from LRTI originating in hospitalized children, as Chong et al. (1997) indicated an increase in LRTIs in hospitalized chil-

dren from 11.4% (in 1988) to 34.7% (in 1995), a result possibly due to the increasing penicillin resistance observed in *M. catarrhalis* isolates over this period.

ADULT INFECTIONS

Bronchitis and Pneumonia Though not a common cause of lower respiratory tract infection in healthy adults, *M. catarrhalis* may present a particular problem for adults with pre-existing pulmonary disease and in the elderly. In particular, bacterial exacerbations of chronic obstructive pulmonary disease (COPD) are often attributable to *S. pneumoniae*, nontypeable *H. influenzae*, and *M. catarrhalis* infection in that order (McLeod et al., 1986; Nicotra et al., 1986; Pollard et al., 1986; Boyle et al., 1991; Eller et al., 1998; Miravittles et al., 1999; Anthonisen, 2002; Sethi et al., 2002).

Bacterial pneumonias attributable to *M. catarrhalis* tend to be relatively mild, with the presence of patchy noncavitary infiltrates on chest X-ray (Wright and Wallace, 1989). Particularly susceptible to *M. catarrhalis* pneumonia are patients with end-stage pulmonary or malignant disease (Hager et al., 1987; Barreiro et al., 1992), and many of these (>70%) are, or have been, smokers (DiGiovanni et al., 1987). *Moraxella catarrhalis* pneumonia may occasionally be complicated by bacteremia (Collazos et al., 1992; Ioannidis et al., 1995; Thorsson et al., 1998).

Klingman et al. (1995) indicated that a proportion (approximately 20%) of *M. catarrhalis*-mediated bronchiectasis patients may be chronically colonized with up to four different strains of *M. catarrhalis*, though a direct relationship between the exacerbation of bronchiectasis and *M. catarrhalis* isolation was not proven.

Laryngitis *Moraxella catarrhalis* appears to be the most frequent bacterial pathogen associated with laryngitis in adults (Schalen, 1988; Schalen et al., 1992; Schalen et al., 1993), though some debate remains as to whether the organism actually infects or simply colonizes adults presenting with laryngitis (Hol et al., 1996). Further, the pathogenic potential of *M. catarrhalis* in laryngitic disease has been suggested by the fact that laryngitis has been induced in an animal model (Jecker et al., 1999) and patients with laryngitis are more likely to harbor isolates presenting with a complement-resistant phenotype (Hol et al., 1996).

Carriage and Spread

Moraxella catarrhalis is an organism able to colonize the human respiratory tract without causing disease, though a striking difference exists

between the carriage rates of *M. catarrhalis* in children and in adults. In children, the carriage rate may be as high as 75% (Van Hare et al., 1987; Faden et al., 1994a; Varon et al., 2000; Garcia-Rodriguez and Fresnadillo Martinez, 2002), while in adults the carriage rate is very low at around 1–3% (Denamur et al., 1991; Ejlersen et al., 1994a). This inverse relationship between rate of colonization and age has been known for approximately 100 years (Arkwright, 1907) and is still present today, though an adequate explanation for this phenomenon still remains elusive. On the basis of the evidence provided by Meier (2003) and Stutzmann Meier (2003), one possible explanation for this phenomenon is that colonization is dependent upon the development of strain-specific mucosal immunoglobulin A (IgA), with specific IgA production perhaps being more important than specific IgG production (Ejlersen et al., 1994b). In this scenario, multiple colonization and infection with different isolates of *M. catarrhalis* gradually increases the repertoire of specific neutralizing IgA (or IgG) antibodies, such that the number of novel *M. catarrhalis* isolates able to colonize a particular individual decreases with time. Alternatively, otitis prone children may fail to produce a broadly protective antibody response (Faden, 2001) or could possibly have (subclinical) deficiencies in immune modulatory genes. Whatever the explanation, the frequency of colonization appears to be distinctly correlated with the development of disease in children (Brorson and Malmvall, 1981; Van Hare et al., 1987; Faden et al., 1990; Faden et al., 1994a; Prellner et al.,

1994), a correlation that may also hold true for adults (Klingman et al., 1995; Murphy, 1998).

The mechanism of spread of *M. catarrhalis* is still debatable, with possible mechanisms including person-to-person transmission or spread via environmental contamination (Calder et al., 1986; McLeod et al., 1986; Ikram et al., 1993; Hays et al., 2003a). Both nursery schools and day care centers may be important reservoirs for strain exchange in children (Prellner et al., 1984; Yano et al., 2000; Masuda et al., 2002), and intrafamilial spread has been observed (Faden et al., 1994a). Outbreaks of nosocomial infection due to *M. catarrhalis* have been regularly documented (Haddad et al., 1986; Patterson et al., 1988; Berk and Verghese, 1989; Cook et al., 1989; Denamur et al., 1989; Richards et al., 1993; Hays et al., 2003a; Masaki et al., 2003; Fig. 4). However, the degree of (nosocomial) spread may be somewhat underestimated because *M. catarrhalis* colonization does not always appear to lead to the appearance of overt disease (Ikram et al., 1993; Hays et al., 2003a).

Antibiotic Susceptibility

Moraxella catarrhalis exhibits an almost universal resistance to penicillin-related antibiotics, with several recent studies indicating that, worldwide, 90–100% of *M. catarrhalis* isolates produce β -lactamase (Jorgensen et al., 1990; Wallace et al., 1990; Manninen et al., 1997; Zhanel et al., 2000; Abe et al., 2002; Memish et al., 2002; Jones et al., 2003). This is a striking statistic when one considers that before 1970 few isolates produced

Fig. 4. Timeline showing dynamic population changes between *M. catarrhalis* pulsed field gel electrophoresis (PFGE) types E and M in a pediatric intensive care unit in the Netherlands (see also Fig. 3). Filled rectangles = child not yet born. Letters = pulsed field electrophoresis type assigned. p23 = child number 23. * = both PFGE types E and M were isolated during these months. # = isolate cultured from a child who had previously been admitted to pediatric intensive care, but at the time of *M. catarrhalis* culture, was present on an unrelated child health ward (none of the other children had been admitted to this particular child health ward). (From Hays et al., 2003a, with permission.)

β -lactamase enzymes (Wallace et al., 1989; Catlin, 1990). In fact, the increase in β -lactamase producing isolates has been so rapid that in most countries, a "saturation point" appears to be being reached, with the increase in incidence of β -lactamases positive *M. catarrhalis* strains now leveling off (at this very high level; Shurin et al., 1983; Zhanel et al., 2000; Jones et al., 2002). Research into *M. catarrhalis* β -lactamase production has shown that three different isotype groups may be identified, BRO-1, BRO-2 and BRO-3 (Eliasson and Kamme, 1985; Labia et al., 1986; Christensen et al., 1991). However, by far the most common types are BRO-1 and BRO-2, which are found in approximately 94% and 5% of β -lactamase producers, respectively (Chaibi et al., 1995). There is some suggestion that BRO-1 is gradually replacing BRO-2 over time (Bootsma et al., 2000b; Richter et al., 2000; Ewy and Walker, 2004) and that BRO-1 producing strains are less susceptible to penicillins than BRO-2 producing isolates (Ikeda et al., 1993). Both BRO-1 and BRO-2 enzymes appear to be constitutively expressed, chromosome- or plasmid-encoded proteins, which differ by a single amino acid (Eliasson and Kamme, 1985; Kamme et al., 1986; Eliasson et al., 1992; Bootsma et al., 1996). Interestingly, some evidence suggests that the BRO β -lactamases of *M. catarrhalis* were originally derived from a non-*Moraxella* species; this evidence includes the lower G+C content of the BRO-encoding (*bla*) genes (31% compared to an average of 41%), and the fact that the BRO-type β -lactamases are lipidated in *M. catarrhalis* (suggesting a Gram-positive origin for the gene; Wallace et al., 1989; Bootsma et al., 1999). A simple restriction digestion methodology to distinguish between the BRO-1 and BRO-2 β -lactamase types has been published (du Plessis, 2001). Of clinical relevance, isolates harboring the BRO-1 encoding gene tend to have higher transcription rates (and hence higher MICs) than BRO-2 harboring isolates (McGregor et al., 1998; Kadry et al., 2003). However, both BRO-1 and BRO-2 enzymes are inactivated by β -lactamase inhibitors (Francioli, 1991; Brook and Van de Heyning, 1994; Oguri et al., 2002). In any case, the choice of treatment should ideally be based upon the type of disease and condition of the patient (e.g. simple or complicated COPD; Murphy and Sethi, 2002). It is perhaps prudent for clinicians to assume that all isolates of *M. catarrhalis* are resistant to penicillin, ampicillin, amoxycillin, piperacillin and cephalothin (Livermore, 1995; Doern et al., 1996; Kadry et al., 2003). Also important for clinicians to consider is the fact that the genes for BRO-type enzymes may be easily transferred by conjugation between different species (Kamme et al., 1984; Wallace et al., 1989), a phenomenon

that may be important in the treatment of mixed infections and may occasionally result in treatment failure (Stefani et al., 1991; Hol et al., 1994; Patel et al., 1995). Interestingly, there is evidence suggests that β -lactamase-producing *Moraxella catarrhalis* may prevent the emergence of penicillin-resistant *Streptococcus pneumoniae* in children with recurrent acute otitis media (Joki-Erkkila et al., 2002).

Moraxella catarrhalis isolates may also show some inherent resistance to trimethoprim, with a recent study of 76 clinical isolates from Saudi Arabia indicating that 14.5% of isolates were resistant to this antibiotic (Kadry et al., 2003). Further, a recent survey showed that approximately 10.5% of *M. catarrhalis* isolates in Latin America (Johnson et al., 2003) and all isolates from an Indian study (Tabassum and Ahmed, 2002) were highly resistant to combination therapy using trimethoprim and sulfamethoxazole. In general, however, *M. catarrhalis* isolates are consistently susceptible to most non- β -lactamase antibiotics including chloramphenicol, erythromycin, ciprofloxacin and gentamicin (Hoban et al., 2001; Bell et al., 2002; Hoban and Felmingham, 2002). Also, fluoroquinolones remain very active against *M. catarrhalis* (Deshpande and Jones, 2000; Esposito et al., 2000). New antibiotics for use against lower respiratory pathogens (including *M. catarrhalis*) are under constant development and testing (Boswell et al., 2002; Jones, 2002).

Immune Responses

The immune response to bacterial pathogens is a highly complex process involving both nonspecific and specific mechanisms.

The Nonspecific Immune Response

Nonspecific mechanisms include the presence of mucus and surfactant at pulmonary surfaces, mucociliary action, alveolar macrophage activity, and complement-mediated lysis (Toews et al., 1990). Onofrio et al. (1981) published data looking at the removal of several bacterial species from the lungs of mice, and in contrast to non-typeable *H. influenzae* and *Streptococcus* spp., found that *M. catarrhalis* was cleared relatively slowly from the lungs with a correspondingly significant increase (400X) in the numbers of granulocytes. Further, the release of neutrophil defensins (peptides exhibiting broad-spectrum antimicrobial activity released by neutrophils as part of the inflammatory process) has been shown to actually stimulate adherence of *M. catarrhalis* (conceivably involving the phase variable expression of bacterial adherence genes;

Gorter et al., 2000). Finally, *M. catarrhalis* has recently been reported to induce mast cell activation and nuclear factor kappa B-dependent cytokine (IL-6 and MCP-1) synthesis by direct contact with the mast cells (with neither bacterial lipopolysaccharide or bacterial supernatants inducing cytokine secretion; Krishnaswamy et al., 2003). The role of complement and complement resistance in *M. catarrhalis* mediated infections is discussed later.

The Specific Immune Response

Several studies have demonstrated the presence of bactericidal antibodies in *M. catarrhalis* associated infections, including: AOM (Leinonen et al., 1981; Faden et al., 1992b; Faden et al., 1994b; Mathers et al., 1999), lower respiratory tract infections (Chapman et al., 1985; Black and Wilson, 1988; Christensen et al., 1996), pneumonia (Gabre-Selasie, 1998) and exacerbations of COPD (Bakri et al., 2002). Using whole-cell *M. catarrhalis* bacteria as coating antigen and an ELISA assay format, Goldblatt et al. (1990) showed that in the majority of cases, normal human sera tested positive for the binding of IgG₁, IgG₂ and IgG₃ subclasses but not IgG₄. Further, the IgG₃ subclass of antibody may be particularly important in *M. catarrhalis* infection (Rahman et al., 1997) as IgG₃-specific antibodies are low or undetectable in children under 4 years of age (Goldblatt et al., 1990b; Chen et al., 1999a). These findings may explain the differences in colonization rates observed between children and adults (Arkwright, 1907; Faden et al., 1994a). However, studies have indicated that host Gm allotype (i.e. genetic markers present on IgG molecules) may influence the IgG subclass composition of specific antibody responses to *M. catarrhalis* outer membrane proteins (Carson et al., 1994), possibly via a complex interaction between B-cells, T-cells, HLA type, and Gm-linked V region antibody expression (Goldblatt et al., 1994). If the IgG₃ subclass is particularly important, and allotype variation results in differences in IgG₃ expression in certain individuals, then this could explain why some children suffer from chronic *M. catarrhalis* infections (e.g., chronic otitis media).

At mucosal surfaces, IgA antibody responses predominate, and specific IgA has been detected in middle ear effusions of children with otitis media (Karjalainen et al., 1991; Faden et al., 1992b; Takada et al., 1998) as well as in the saliva of healthy adult volunteers (Meier et al., 2003). Stutzmann Meier et al. (2003) indicated that *M. catarrhalis* colonization in early infancy was associated with a consistent IgA immune response directed against the outer membrane proteins. However, the development of (mucosal) IgA

antibody may not necessarily correspond to the development of (systemic) IgG antibody (Stenfors and Raisanen, 1993; Samukawa et al., 2000a). Of note, Mandrell (1992) and Troncoso et al. (2004) identified cross-reactive antigens between *M. catarrhalis*, *N. meningitidis* and *N. lactamica* and showed the presence of cross-reactive antibodies in both healthy individuals and patients convalescing from meningococcal meningitis.

Vaccines

Currently, the efforts of many researchers in the *M. catarrhalis* field is geared towards the identification and development of specific vaccine candidates (reviewed in McMichael [2000a], McMichael [2000b] and McMichael and Green [2003]) with particular emphasis being placed on 1) the lipooligosaccharide/lipopolysaccharide (LOS/LPS) and 2) various highly expressed outer membrane proteins (OMPs; Murphy, 1989a).

Several studies have indicated that an antibody response to the LPS of *M. catarrhalis* is generated and that this response is not serotype specific but directed against common epitopes present on the LPS (Fomsgaard et al., 1991; Rahman et al., 1995; Oishi et al., 1996; Jiao et al., 2002). However, confusingly, some evidence suggests that the antibody response (in rabbits) is indeed serotype specific (Rahman and Holme, 1996). This LPS antibody response appears to be particularly directed against the oligosaccharide region of the LPS (Edebrink et al., 1994; Edebrink et al., 1995; Edebrink et al., 1996). The inoculation of nonviable *M. catarrhalis* into the middle ear bullae of guinea pigs also induces middle ear inflammation and mucoperiosteal histopathology, a type of inflammatory picture most probably mediated by bacterial outer membrane components (including the LOS; Sato, 1997). On the basis of this data, research by several groups has indicated that the LPS/LOS may be a promising vaccine candidate so long as its inherent toxicity is removed and it is linked to a protein conjugate to improve immunogenicity (Tanaka et al., 1992; Gu et al., 1998; Hu et al., 2000; Jiao et al., 2002). To complicate matters, the immunospecificity of at least three serotypes of LPS, each exhibiting some form of crossreactivity (Vanechoutte et al., 1990), may depend on differences in the lengths of the immunodominant oligosaccharides (Edebrink et al., 1996). However, no relationship between serotype and severity of infection has been noted, implying that all three of these common LOS serotypes (types A, B and C) should ideally be included in a future LPS/LOS based vaccine (Fig. 5).

Fig. 5. Schematic structure of the lipooligosaccharide moieties from the three main serotypes (A, B and C) of *Moraxella catarrhalis*. Serotype differences are related to differences in the nature of the "R"-group. (From Verduin et al., 2002, with permission.)

Most research regarding the development of a vaccine against *M. catarrhalis* has concentrated on the identification and investigation of several major OMPs, which currently fall into roughly two distinct groups. One group includes OMPs associated with bacterial adherence, including: UspA1/2 (Helminen et al., 1994; Chen et al., 1996; Chen et al., 1999a; Aebi et al., 1997), OMP CD (Murphy et al., 1993; Yang et al., 1997; Murphy et al., 2003) and MID (Forsgren et al., 2001; Forsgren et al., 2003), while the other group includes OMPs associated with iron and fatty acid (nutrient) acquisition, LbpA, LbpB, TbpA, TbpB/B1/74-kDa protein (Bonnah et al., 1995; Bonnah et al., 1998b; Campagnari et al., 1996; Mathers et al., 1997; Bonnah and Schryvers, 1998a; Chen et al., 1999b), CopB (Helminen et al., 1993; Aebi et al., 1996; Sethi et al., 1997) and OMP E (Bhushan et al., 1994; Murphy et al., 2000).

The UspA proteins (UspA1 and UspA2) are closely related proteins that share some conserved, semiconserved, and repeat sequence domains (Aebi et al., 1997; Cope et al., 1999; Hays, 2003). Both proteins share a conserved epitope that binds the monoclonal antibody 17C7 (mab17C7), which could be useful in the progress towards a *M. catarrhalis* vaccine (Meier et al., 2002). Moreover, both proteins appear to elicit (protective) antibodies in humans (Chen et al., 1999a; Samukawa et al., 2000a; Samukawa et al., 2000b; Stutzmann Meier et al., 2003), mice (Helminen et al., 1994; McMichael et al., 1998), and guinea pigs (Chen et al., 1996). OMP CD is a protein shown to specifically bind human middle ear and nasal mucins but not salivary mucin (Reddy et al., 1997), and exhibits a high degree of sequence conservation (Yang et al., 1997;

Murphy et al., 1999). The protein has also been shown to be a target for both the mucosal and systemic immune response (Murphy et al., 2003). However, the degree of sequence conservation in OMP CD could indicate that this protein does not actually come under immunoselective pressure in vivo and may therefore not actually be a good vaccine candidate in humans. A recent study has also indicated that a 200-kDa IgD binding protein (MID) is also an adhesin (Forsgren et al., 2003), which is able to induce human B-lymphocyte (but not T-lymphocyte) activation (Gjorloff Wingren et al., 2002). This protein also appears to be conserved and is apparently present in most *M. catarrhalis* isolates (Mollenkvist et al., 2003). However, the usefulness of this MID protein as a future vaccine candidate has yet to be determined.

Studies have shown that *M. catarrhalis* expresses two lactoferrin receptors (LbpA and LbpB; Bonnah et al., 1999) and two transferrin receptors (TbpA and TbpB/OMP B1; Myers et al., 1998). Yu et al. (1999) showed that of these four iron acquisition proteins, only the LbpB and TbpB proteins show strong reactivity with acute- and convalescent-phase sera from patients with *M. catarrhalis*-associated pulmonary infections. Moreover, the antigenic heterogeneity in reactivity to the TbpB and LbpB proteins isolated from different *M. catarrhalis* strains appeared to be considerable. CopB (also known as OMP B2) is an iron-repressible 81-kDa outer membrane protein, which is largely conserved between *M. catarrhalis* isolates with discrete regions of moderate heterogeneity (Sethi et al., 1997). A copB binding monoclonal antibody (Mab10F3) was shown to enhance the pulmonary clearance of *M. catarrhalis* in a mouse model and was able to bind to 70% of *M. catarrhalis* isolates tested (Helminen et al., 1993; Aebi et al., 1998a). Moreover, significant rises in anti-copB antibody titers were observed in patients with *M. catarrhalis* infections (Helminen et al., 1995; Mathers et al., 1999; Meier et al., 2003). OMP E exhibits weak homology to the fatty acid transporter FadL of *E. coli* (Bhushan et al., 1994). The 47-kDa protein appears to be highly conserved among *M. catarrhalis* isolates (Murphy et al., 2001), and a majority of patients with chronic bronchitis were shown to have IgA antibodies to OMP E in their sputum (though surprisingly none of ten adults with *M. catarrhalis* lower respiratory tract infections demonstrated a clear-cut rise in OMP E antibody titer; Bhushan et al., 1997). Further, two *M. catarrhalis* gene knockout mutants lacking OMP E were shown to be more readily killed by normal human serum compared to the isogenic parent strains (Murphy et al., 2000). The possible role of these proteins as potential vaccine candidates is also under investigation.

Note that several groups have independently worked with the TbpB protein, such that two other names exist for TbpB, namely "B1" (Campagnari et al., 1996) and "74K protein" (Chen et al., 1999b).

Physiology

LIPOLYSACCHARIDE AND LIPOOLIGOSACCHARIDE

The lipopolysaccharide (LPS) and lipooligosaccharide (LOS) bacterial surface components are major virulence factors of Gram-negative bacteria, and in *M. catarrhalis* the LOS has been shown to be an important cell wall structural component (Luke et al., 2003). Biochemically, the LOS of *M. catarrhalis* isolates appears to contain no O-chain polysaccharide (Campagnari et al., 1990; Holme et al., 1999) and is of the "semi-rough" type (Fomsgaard et al., 1991). Vaneechoutte et al. (1990) were able to distinguish three different LOS types, namely types A (60%), B (30%) and C (5%). These three different types corresponded to different LOS chemical structures, all containing a common polysaccharide core but showing differences in terminal sugar groups in one of the LOS branches (Edebrink et al., 1996; Holme et al., 1999). Specifically, type B oligosaccharides contain a 4-substituted α -D-glucopyranosyl residue (α -D-Galp) instead of 2-acetamido-2-deoxyglucopyranosyl residues (α -D-GlcpNAc). Significant levels of variation have also been reported in the lipid A region of the LPS (Kelly et al., 1996). Interestingly, the nonenteric, Gram-negative bacteria *M. catarrhalis*, *H. ducreyi*, *H. influenzae*, *N. gonorrhoeae* and *N. meningitidis* possess LOS with similar structures (Campagnari et al., 1990) and in particular a terminal trisaccharide (α -D-Galp-(1 \rightarrow 4)- β -D-Galp-(1 \rightarrow 4)- α -D-Glcp-(1 \rightarrow 2)), which is also found as the terminal part of glycolipids on the surface of human epithelial cells of mucous membranes (Holme et al., 1999). Moreover, the α -D-Galp-(1 \rightarrow 4)- β -D-Galp component of this trisaccharide has already been implicated in bacterial pathogenesis (Virji et al., 1990).

PEPTIDOGLYCAN AND CAPSULE

The peptidoglycan layer of *M. catarrhalis* was first described by Hellio et al. (1988). This layer forms part of the *M. catarrhalis* cell envelope, and as yet very little is known regarding the role of this peptidoglycan in the immune response to *M. catarrhalis*. Keller et al. (1992) showed that *M. catarrhalis* peptidoglycan was similarly active to the peptidoglycans of *Staphylococcus aureus* and *Bacillus subtilis* in triggering the secretion of tumor necrosis factor and the tumoricidal activity of macrophages but noted that *M. catarrhalis* pep-

tidoglycan was particularly potent in its ability to induce the generation of nitrite in macrophages.

Capsules are composed of a layer of polysaccharide surrounding the bacterial cell, which are known to be important virulence factors in both Gram-positive and Gram-negative bacteria. The presence of a capsule in *M. catarrhalis* has previously been suggested (Ahmed et al., 1991), though no capsule is observed when colonies of *M. catarrhalis* grown on agar plates are examined.

ATTACHMENT PILI AND FIMBRIAE

Pili and fimbriae are used by bacteria as attachment mechanisms, allowing them to adhere to mucosal epithelial cells. Confusingly, evidence suggests the presence of both type 4 (MePhe) and a non-type 4 class of pili (Marrs and Weir, 1990), as well as evidence for a lack of pili in *M. catarrhalis* (Ahmed et al., 1991; Rikitomi et al., 1991). These results may indicate either 1) that some strains possess pili whereas others do not, or 2) that some form of phase available expression system of pili genes occurs (as observed with *M. bovis*). Both fimbriated and nonfimbriated isolates of *M. catarrhalis* have been described, and a role for fimbriae in cellular adherence has been supported by a reduction in adherence after various treatments that denatured the fimbriae, or after binding of antifimbrial antibodies (Rikitomi et al., 1991). In a later study, increased binding to lower airway bronchial epithelium cells was observed for fimbriated strains as opposed to a nonfimbriated strain (Rikitomi et al., 1989). Fimbrial adhesion is apparently mediated via ganglioside M2 sequences in the host cell receptor (Ahmed et al., 1996).

OUTER MEMBRANE PROTEINS

Initial studies into the outer membrane proteins of *M. catarrhalis* has revealed the presence of eight major proteins (OMPs A to H) varying in size from 21 kDa to 98 kDa, all exhibiting a relatively high degree of interstrain similarity (Bartos and Murphy, 1988; Murphy and Loeb, 1989b; Murphy, 1990). This interstrain similarity means that serological OMP profiling probably has limited use in distinguishing between individual *M. catarrhalis* isolates, though it does suggest that these proteins may be suitable as vaccine candidates. The exact function of the majority of these OMPs is as yet unclear.

OMP B2 or copB is an 81-kDa OMP that is largely conserved between *M. catarrhalis* isolates and displays discrete regions of moderate heterogeneity (Sethi et al., 1997). The expression of copB increases under iron-limiting conditions (Aebi et al., 1996), and in vitro, the protein has been shown to have the ability to bind to iron-

laden lactoferrin (Bonnah et al., 1998b). CopB therefore appears to be involved in *M. catarrhalis* iron-acquisition.

Originally considered as two distinct proteins, OMPs C and D actually represent two different yet stable forms of the same protein (protein CD; Murphy et al., 1993). Moreover, though calculated to have a molecular mass of 46 kDa, the presence of a proline-rich region means that OMP CD has an apparent mass of 60 kDa upon sodium dodecylsulfate-polyacrylamide gel electrophoresis (SDS-PAGE). OMP CD may play a role in cell adhesion, as it has been found to specifically bind to human middle ear and nasal (but not salivary) mucins (Reddy et al., 1997). Further, studies have indicated that the gene encoding OMP CD exhibits a high degree of homology (Hsiao et al., 1995) and that the protein is an interesting vaccine candidate (Yang et al., 1997; Murphy et al., 1999).

OMP E is an apparently highly conserved 50-kDa protein (Murphy et al., 2001) that exhibits the trimeric structure of many porins (Bhushan et al., 1994). OMP E shows weak homology to the FadL fatty acid binder and transporter of *E. coli* (Bhushan et al., 1994) and may be involved in the uptake of nutrients (e.g., fatty acids).

As well as the 8 OMPs originally identified, an extra OMP was found in the *M. catarrhalis* cell wall by Klingman and Murphy (1994). Originally called "HMW-OMP" because of its higher molecular weight (greater than 250 kDa), this OMP is most likely composed of oligomers of ca. 120–140 kDa. Later studies revealed that HMW-OMP was actually encoded by two different genes that shared a 140-amino acid region (homology = 93%) and a common monoclonal antibody epitope (Aebi et al., 1997). These genes encoded two distinct oligomeric proteins named "UspA1" (ubiquitous surface protein A1) and "UspA2" (ubiquitous surface protein A2), with calculated protein masses of only 88 kDa and 66 kDa, respectively. The apparent difference between calculated and observed mass upon SDS-PAGE is due to the formation of coiled coil structures and dimer formation in the final proteins (Hoiczky et al., 2000). Physiologically, UspA1 appears to be involved in cellular adhesion and is capable of binding fibronectin (Aebi et al., 1998b; McMichael et al., 1998), while UspA2 appears to be mainly involved in resistance to complement (Verduin et al., 1994a; Verduin et al., 1994b; Aebi et al., 1998b). Both *uspA1* and *uspA2* genes possess several common amino acid repeat motifs in their open reading frames (ORFs) and possess either a homopolymeric poly-G tract (*uspA1*) or a poly-AGAT repeat sequence (*uspA2*) in their 5' ORF promoter sequences, which may be linked to phase vari-

able gene expression (Aebi et al., 1997; Lafontaine et al., 2001). The structure and function of the *M. catarrhalis* UspA1 and UspA2 proteins share some similarity with the adhesin protein (YadA) of *Yersinia enterocolitica* (Hoiczky et al., 2000).

Iron acquisition is an important factor in bacterial survival, and *M. catarrhalis* produces both lactoferrin (LbpA and LbpB) and transferrin (TbpA and TbpB/OMP B1) receptor proteins (Yu and Schryvers, 1993; Bonnah et al., 1999). The LbpA and LbpB proteins have been sequenced and cloned (Du et al., 1998), and isogenic mutants of these genes show a reduced binding affinity for lactoferrin (Bonnah et al., 1999). The *tbpA* gene appears to be highly conserved, which contrasts with the *tbpB* gene, which is markedly heterogeneous (Myers et al., 1998). Luke et al. (1999) showed that the TbpA protein was necessary for the acquisition of iron from transferrin, yet the TbpB protein was not essential. They suggested that the function of TbpB might be to optimize the TbpA/transferrin interaction. A detailed map of peptide-peptide interactions between human transferrin and TbpB from *Moraxella catarrhalis* was recently presented by Sims and Schryvers (2003).

Recently, a 200-kDa immunoglobulin D (IgD)-binding outer membrane protein (MID) was identified by Forsgren (Forsgren et al., 2001) and later shown to be involved in both 1) the binding of *M. catarrhalis* to type II alveolar epithelial cells, and 2) the agglutination of human erythrocytes (Forsgren et al., 2003). The MID proteins from five different *M. catarrhalis* strains exhibited 71–89% similarity (Mollenkvist et al., 2003). The protein requires a tetrameric formation for optimal IgD-binding capacity (Nordstrom et al., 2002), and as with the *M. catarrhalis* *uspA1* gene, the *mid* gene also possesses several amino acid repeat motifs and a homopolymeric poly-G tract in its promoter region (Mollenkvist et al., 2003), indicating that phase variable gene expression occurs.

Virulence Traits

According to Smith (1995), there exists five basic requirements involved in bacterial virulence, namely the ability to 1) bind, colonize and infect mucosal surfaces, 2) enter host tissues, 3) replicate in vivo, 4) interfere and possibly inhibit host defense mechanisms, and 5) damage the host organism. Much remains to be discovered about these virulence mechanisms in *M. catarrhalis*, though the presence of phase-variable virulence genes homologous to phase variable virulence genes of *H. influenzae*, has been noted (Peak et al., 1996).

PHASE VARIABLE GENE EXPRESSION The presence of repeat DNA sequences in the promoter regions of virulence genes of *M. catarrhalis* has been demonstrated. These sequences could influence gene expression in a phase variable manner (i.e. where differences in promoter repeat unit number in subsequent progeny bacteria affect the level of gene expression within these progeny bacteria). Seib et al. (2002) have discovered 5'-CAAC-3' repeat unit elements in the 5'-coding start region (the methylase components) of two distinct type III restriction-modification (R-M) systems. Such systems act to limit the integration of foreign DNA into the bacterial chromosome and may have an important role in the biology of *M. catarrhalis*. In a separate study, Peak et al. (1996) also discovered and assigned a role for 5'-CAAC-3' repeat sequences with virulence factor gene phase variation in *M. catarrhalis*.

The *Moraxella catarrhalis* IgD-binding outer membrane protein MID contains a homopolymeric polyguanine (poly-G) tract in its promoter region (Forsgren et al., 2001). Moreover, all isolates expressing high levels of MID had 1, 2 or 3 triplets of Gs in their poly(G) tracts, while strains not expressing MID had 4, 7, 8 or 10 Gs in their poly-G tracts (or else point mutations that prematurely terminated the protein; Mollenkvist et al., 2003). The MID protein is an adhesin allowing *M. catarrhalis* to bind to host epithelia and interestingly the UspA1 protein (another adhesin) also contains a poly-G tract (in this case in the promoter region). Though the mechanism of action may be different, phase variable expression of both of these poly(G)-tract-containing genes probably occurs. In contrast to the UspA1 protein, the similar *uspA2* gene has been shown to contain variable numbers of AGAT-repeat unit sequences in its promoter region (Aebi et al., 1997; Hays et al., 2003a), sequences that again could affect the level of gene expression for this protein, a protein implicated in complement resistance.

BACTERIAL ADHERENCE Bacterial adherence is a virulence factor that allows the organism to remain in situ on epithelial cells despite the action of nonspecific host defense mechanisms (e.g. the action of cilia, coughing, etc.).

However, Kyd et al. (1998) demonstrated that a nonaggregating (reduced expression of outer membrane proteins) variant of *M. catarrhalis* was less rapidly cleared in a mouse model compared to the aggregating parental strain.

Ahmed et al. (2002) showed that *M. catarrhalis* can bind to asialo-GM1 (Gg4Cer) and asialo-GM2 (Gg3Cer) gangliosides, which both contain a common GalNAc β 1 \rightarrow 4Gal β 1 sequence. This sequence has been shown to act as a receptor attachment site for many respiratory bacteria.

Several OMPs of *M. catarrhalis* have been implicated in facilitating bacterial adherence to host epithelia, including UspA1 (Aebi et al., 1998b) and hemagglutinin (Hag) proteins (Holm et al., 2003). UspA1 (>250 kDa) is a lollipop shaped protein present on the bacterial surface, which interacts with fibronectin (McMichael et al., 1998), and binds to carcinoembryonic antigen-related cell adhesion molecules (receptors for several *Neisseria* and *Haemophilus* spp.) on the surface of human respiratory epithelial cells (Hill and Virji, 2003). The Hag protein is also a high molecular weight protein (200 kDa), which has some similarity to the IgD binding protein (MID; Fitzgerald et al., 1997) of *M. catarrhalis*, and has recently been shown to be an adhesin for cell lines derived from human lung and middle ear tissues (Holm et al., 2003). The Hag protein also has the potential to interact with both the UspA1 and UspA2 proteins as well as with host defense mechanisms (Pearson et al., 2002). Perhaps the most widely studied adhesion interaction has been that between OMP CD and host epithelia. Reddy et al. (1997) indicated that OMP CD was capable of interacting with the middle ear mucin glycoprotein (but not asialomucin), and Bernstein and Reddy (2000) indicated that the OMP CD-mucin interaction is dependent on the site where the mucin was produced, binding to mucin from the nasopharynx and middle ear but not to mucin from the tracheobronchus or saliva. More recently, Forsgren et al. (2003) demonstrated that an IgD binding protein (MID) present on the surface of *M. catarrhalis* was capable of binding to type II alveolar epithelial cells, and that mutants deficient in MID had a 50% lower adhesive capacity, even in the presence of detectable UspA1 expression. Timpe et al. (2003) recently screened for novel adhesins in *M. catarrhalis* and discovered a new potential adhesin protein (named "*M. catarrhalis* adherence protein" or "McaP"), which exhibited substantial similarity to the GDSL family of lipolytic enzymes. Finally, host factors have been shown to play a role in *M. catarrhalis* adherence to respiratory cells. In particular, attachment is increased when cells have been exposed to cigarette smoke (Kurtti et al., 1997), a response apparently not attributable to enhanced expression of host cell antigens (El Ahmer et al., 1999).

SERUM AND COMPLEMENT RESISTANCE The complement system is a complex series of serum proteins, which are part of the host defense mechanism against microbial pathogens (Cates, 1983; Loos and Clas, 1987). The ability of Gram-negative bacteria to withstand the effects of complement is an important virulence factor (Roantree and Rantz, 1960; Brown et al., 1983), and many *M. catarrhalis* disease-causing isolates

are apparently resistant to the effects of complement in human serum (Jordan et al., 1990; Hol et al., 1993; Hol et al., 1995). Several studies have shown the importance of complement resistance to *M. catarrhalis* pathogenicity (Brorson et al., 1976; Soto-Hernandez et al., 1989; Murphy et al., 1997), with isolates from the upper respiratory tract of children or healthy adults tending to be complement sensitive, whilst isolates from children and adults with lower respiratory tract infections tend to be complement resistant (Hol et al., 1995; Verduin et al., 2002). β -Lactamase production (another virulence factor) does not appear to be related to complement resistance in *M. catarrhalis* (Schmitz et al., 2002), possibly reflecting the plasmid borne nature of β -lactamase production or the multifactorial nature of complement resistance. Our knowledge regarding complement resistance mechanisms in *M. catarrhalis* is as yet limited. Prellner (1980) provided evidence for high level binding of C1q complement component to *M. catarrhalis*, a phenomenon that would render the organism sensitive to the antibacterial activity of complement. Research by Verduin et al. (1994a) showed that at least one resistance mechanism involves inhibition of formation of the membrane attack complex of complement and the binding of vitronectin (a natural inhibitor of complement found in serum) to the UspA2 protein present on the surface of *M. catarrhalis* (Verduin et al., 1994b; McMichael et al., 1998). An *M. catarrhalis* mutant lacking the *uspA2* gene was found to be sensitive to complement-mediated killing, while the parent isolate was resistant (Aebi et al., 1998b). Further, UspA2 protein shares similarity with the *H. ducreyi* DsrA (*ducreyi* serum resistance protein A), which has also been shown to be involved in serum resistance (Cole et al., 2002). A *copB* gene knockout *M. catarrhalis* mutant was used by Helminen et al. (1993) to show that reduced expression of the CopB (or OMP B2) iron acquisition protein decreased serum resistance and survival in vivo. Confusingly, however, Furano and Campagnari (2003) recently indicated that constitutive expression of iron-regulated proteins (via inactivation of the ferric iron uptake regulator gene *fur*) actually increases the susceptibility of *M. catarrhalis* to the bactericidal activity of normal human sera and suggested that this most probably occurs because of the upregulated expression of OMPs, increasing the presence of multiple antigenic targets for human antibody binding and hence complement activation. One further study of *M. catarrhalis* OMP expression indicated that OMP E (a putative fatty acid transporter) may be involved in serum sensitivity (Murphy et al., 2000). In 2000, Zaleski et al. (2000) implicated the *M. catarrhalis* LOS in complement resis-

tance, as inactivation of the *galE* gene, which encodes a UDP-glucose-4-epimerase (involved in the biosynthesis of LOS) resulted in enhanced serum susceptibility of the mutant. Interestingly, similarities between *M. catarrhalis* and some more thoroughly studied *Neisseria* spp. (e.g., *N. gonorrhoea* and *N. meningitidis*), with respect to OMPs and LOS, may provide further clues as to the mechanisms by which complement resistance is mediated in *M. catarrhalis*.

Finally, several studies have indicated that complement resistant and complement sensitive isolate of *M. catarrhalis* may actually represent two different subspecies (Verduin et al., 2000; Bootsma et al., 2000a; Bootsma et al., 2000b).

Animal Models and Virulence

One of the earliest reports of an animal model for *M. catarrhalis* was published in 1989 by Doyle et al. (1989), who inoculated *M. catarrhalis* into the middle ear of chinchillas and gerbils facilitating the production of an effusion (containing no live bacteria after 24 h). Further work by Chung et al. (1994) also indicated that the chinchilla model may be useful in studying *M. catarrhalis* infection (specifically otitis media). The majority of *M. catarrhalis* animal model studies have however, focused on the mouse model of infection. Verghese et al. (1990) studied the pulmonary clearance and phagocytic cell response of *M. catarrhalis* in a murine model. In this endotracheal challenge model, a high influx of polymorphonuclear leucocytes into the lungs was observed, with the bacterium being cleared within 24–48 h (though mice with a C5 complement component deficiency showed a minor delay in clearance). Another mouse model utilized transoral inoculation of the lungs (using surgery to expose the trachea) to evaluate the bacterial-lung interaction and observe any pathological changes (Unhanand et al., 1992). Using essentially the same model, MacIver et al. (1993) showed that an enhanced clearance of bacteria from the lungs of infected mice could be obtained after immunization with *M. catarrhalis* derived outer membrane vesicles. Another mode of infection was utilized by Kyd et al. (1999), who directly inoculated killed bacteria into the Peyer's patches of mice followed by an intratracheal booster inoculation. Enhanced clearance of bacteria was observed in the lungs, which correlated to higher levels of specific IgG and IgA in both serum and bronchoalveolar lavage fluid. Hu et al. (Hu et al., 1999; Hu et al., 2000) as well as other researchers (Hou et al., 2002; Jiao et al., 2002) have had some success in developing an inhalation model and using it to assess various immunization strategies. On the whole however, there is still some debate over precisely which

is the best animal model for mimicking *M. catarrhalis*-mediated human infections (Melhus and Ryan, 2003). For example, several recent pathogenesis studies used the rat instead of the mouse as a model of infection (Jecker et al., 1999; Westman et al., 1999; Caye-Thomasen et al., 2000; Kyd and Cripps, 2000), while the development of PCR-mediated detection methodologies have focused on the chinchilla model (Bakaletz et al., 1995; Post et al., 1996; Aul et al., 1998).

Final Comments

Moraxella catarrhalis is now firmly established as a pathogen in its own right, generally facilitating upper respiratory tract disease in children and lower respiratory tract disease in adults. The carriage and spread of *M. catarrhalis* isolates in daycare centers, nursery schools, and in the nosocomial setting has been established, and almost all clinical isolates are now resistant to penicillin-based antibiotics. Currently however, relatively little is known about the mechanisms facilitating virulence in this pathogen. Vaccines against the more prevalent respiratory bacterial pathogens *S. pneumoniae* and *H. influenzae* are presently in an advanced state of development, which if successful, could result in an increase in infections attributed to *M. catarrhalis* in the future (as the organism seeks to fill the empty niche left after vaccination against these two pathogens). With this in mind, further research into a vaccine against *M. catarrhalis*, as well as the virulence mechanisms attributable to this organism, are warranted.

Legionella Species and Legionnaires' Disease

PAUL H. EDELSTEIN AND NICHOLAS P. CIANCIOOTTO

Introduction and History

Parts of this chapter were modified from the same chapter of the previous book edition, written by William Pasculle.

Legionnaires' disease is an acute pneumonic illness caused by Gram-negative bacilli of the genus *Legionella*. Pontiac fever is a febrile, non-pneumonic, systemic illness closely associated with, if not caused by, *Legionella* spp.

Legionnaires' disease was first recognized as a distinct clinical entity when it caused an epidemic of pneumonia at an American Legion convention in Philadelphia in 1976; 221 people were affected, and 34 died (Fraser et al., 1977). Despite intensive laboratory investigation, the cause of the outbreak went undetected for many months. This mystery provoked considerable fear and widespread speculation about the cause, including claims that it was a government plot, a germ warfare experiment, and a toxin. A thorough epidemiologic investigation determined that the disease was most likely airborne, and focused primarily at one convention hotel. The inability to determine the cause of the outbreak confounded politicians and scientists who had thought that there were no new infectious diseases to be discovered. There was enough national and political concern to prompt two independent congressional investigations of the outbreak. About six months later, two investigators at the United States Centers for Disease Control and Prevention (CDC), Joseph McDade and Charles Shepard, announced that they had discovered the etiologic agent, a fastidious Gram-negative bacillus (McDade et al., 1977). Because of the historical association with the American Legion convention, this disease is now called "Legionnaires' disease," and the etiologic agents belong to the family Legionellaceae, with *L. pneumophila* being the agent responsible for the 1976 Philadelphia epidemic.

Use of an antibody test for the disease showed that several prior unsolved outbreaks of pneumonia had been Legionnaires' disease, including epidemics investigated in the 1950s (Osterholm et al., 1983; Stout and Yu, 1997; Broome and

Fraser, 1979; Winn, 1988; Breiman and Butler, 1998). An unsolved epidemic of a nonpneumonic febrile illness was also found to be due to exposure to *Legionella* bacteria; this illness was termed "Pontiac fever," after the city where this had occurred (Glick et al., 1978; Kaufmann et al., 1981). In addition, saved culture isolates from the 1940s through the 1960s were found to be *Legionella* bacteria although at the time they had been thought to be rickettsial agents (Tatlock, 1944; 1947; 1982; Bozeman et al., 1968; Hébert et al., 1980a). Thus both the organism and the disease had previously been studied decades before but had been forgotten. Ever since the 1976 outbreak in Philadelphia, (http://www.q-net.net.au/~legion/Legionnaire's_Disease_CONTENTS.htm {Legionnaires' disease}) has taken on an undeserved reputation of a highly fatal and common disease.

Clinical and Public Health Aspects of Legionnaires' Disease

Clinical Presentation

Legionnaires' disease presents clinically as pneumonia, with features indistinguishable from other common forms of bacterial pneumonia, such as pneumococcal pneumonia (Granados et al., 1989; Roig et al., 1991; Sopena et al., 1998; Tan et al., 2000; Edelstein, 1993a; Edelstein and Meyer, 1995b). There is some suggestion that a combination of factors such as diarrhea, hyponatremia, and increased serum creatine kinase is more consistent with Legionnaires' disease than other pneumonic diseases, but no study has shown this unequivocally. Thus the clinical presentation generally consists of fever, fatigue, often headache or muscle aches and cough. Chest pain, diarrhea, confusion, shaking chills, and shortness of breath also may be seen. The chest roentgenogram usually demonstrates alveolar filling, focal infiltrates, and lung consolidation with or without pleural effusions.

Extrapulmonary infection occurs rarely, either as disseminated infection in patients with pneu-

monia or very rarely as isolated primary infection (Edelstein, 1993a; Stout and Yu, 1997). Isolated disease of prosthetic heart valves, respiratory sinuses, and open wounds have all been reported. Pleural empyema, myocarditis, meningitis, encephalitis, pericarditis, vascular shunt infections, peritonitis and colitis have all been documented to very rarely occur during the course of pneumonia (Edelstein and Meyer, 1995b).

Treatment

Legionnaires' disease is treated with macrolide, tetracycline, or fluoroquinolone antimicrobial agents (Edelstein, 1995a; 1998). All of these agents concentrate within macrophage lysosomes. The drugs of choice to treat mild disease in community-acquired pneumonia include erythromycin, doxycycline, azithromycin and levofloxacin. For severely ill patients, or immunocompromised ones, either azithromycin or levofloxacin are the drugs of choice (Edelstein, 1995a; 1998). Antimicrobial agents that are ineffective include all β -lactam agents and penems, aminoglycosides, glycopeptides and chloramphenicol. The response to treatment depends on the patient's age, underlying diseases, degree of pulmonary involvement, the timing of treatment in relation to disease onset, and severity of disease. Untreated disease is fatal in 5–80% of patients, depending on the above factors; previously healthy people with minimal disease have the best outcome, and otherwise ill or immunocompromised patients with extensive pneumonia the worst outcome. Prompt specific therapy reduces the fatality rate by two- to sixfold. The duration of therapy, depending on the agent used and the presence of immunosuppression, ranges from 3–21 days; patients with endocarditis or cavitating pneumonia may require longer courses of therapy.

Epidemiology

Legionnaires' disease causes both sporadic and epidemic pneumonia worldwide. In the United States, the sporadic form of the disease causes around 10,000 cases of pneumonia per year in adults requiring hospitalization for pneumonia, and perhaps the same number of cases of pneumonia in adults not requiring hospitalization for pneumonia (Marston et al., 1997; Breiman and Butler, 1998). Overall this represents approximately 1–4% of all adult pneumonias in the United States. However in its epidemic form, the disease can be responsible for a large number of cases over a short time period, for example 226 people developed Legionnaires' disease, 18 of whom died, over five days during an epidemic

that occurred at a (<http://www.eurosurv.org/1999/990401.html>{flower show}) in the Netherlands. Such epidemics are fortunately rare, but they do remind us that disease prevention through the use of proper engineering and construction controls and of rapid disease recognition through laboratory testing is important, and that knowledge of the important factors responsible for disease outbreaks is lacking.

Major risk factors for community-acquired Legionnaires' disease include administration of glucocorticosteroid medications and other forms of immunosuppression, cigarette smoking, chronic severe renal failure, age greater than 50 years, AIDS, hematologic malignancies, lung cancer and male gender (Marston et al., 1994). Alcohol abuse may or may not be a significant risk factor (Broome and Fraser, 1979; Marston et al., 1994). The same risk factors seem to apply for nosocomial acquisition, as well as exposure to a known source of the organism (Haley et al., 1979; Shands et al., 1985; Carratala et al., 1994; Joseph et al., 1994). Surgery, or more probably general anesthesia, also has been a risk factor in some nosocomial epidemics of Legionnaires' disease (Serota et al., 1981; Korvick and Yu, 1987).

The incubation period of the disease is about 2–10 days (Breiman and Butler, 1998). The disease is spread primarily via aerosols of contaminated water, although microaspiration also may be an important mode of spread in nosocomial disease (Breiman and Butler, 1998; Blatt et al., 1993; Venezia et al., 1994). The sources of *Legionella*-containing aerosols are usually water-cooled heat rejection equipment such as air-conditioning cooling towers, whirlpool spas, sink taps and shower heads (Brundrett, 1992). Virtually any device that can create an aerosol of warm water can be a disease source, including such equipment as ice machines, vegetable misters, and compressed oxygen humidifiers. The bacterium multiplies best in water at temperatures between about 25–42°, and so to contain high concentrations of the bacterium, the contaminated water must be heated either naturally or by mechanical equipment. A major source of such warm water is a water heater, which often contains several different thermoplanes that do not mix well, leaving pockets of relatively cool water.

Strain typing is often crucial when investigating epidemics of Legionnaires' disease (Mahoney et al., 1992; Mamolen et al., 1993; Pruckler et al., 1995b; Whitney et al., 1997; Brown et al., 1999; Fiore et al., 1998; Joseph et al., 1996; Hunt et al., 1991). These results most often are used to determine the environmental source of an outbreak, as multiple same-species and serogroup culture-positive environmental sites are usually found during outbreak investi-

gations. Generally only one of these sites is linked to the outbreak. A large variety of typing methods can be used in this circumstance. The first and most widely used one was subtyping of *L. pneumophila* serogroup 1 using a monoclonal antibody typing panel (Joly et al., 1986b). Unfortunately some of the hybridomas for making the antibodies are no longer available, so the typing scheme cannot be used as initially proposed. However, enough of the reagents are still available and are used commonly in outbreak investigations by national public health laboratories. Monoclonal typing schemes for other *L. pneumophila* serogroups have been developed, and newer antibody panels have been made to replace the original *L. pneumophila* serogroup 1 panel (Helbig et al., 1994; Lück et al., 1991; 1992; 1995a). Plasmid typing was never very useful for strain subtyping, as many epidemic strains lacked plasmids; even when plasmids were present, the method was slow and technically demanding (Edelstein et al., 1986). However, for plasmid-containing strains there is good correlation with monoclonal typing results. Analysis of chromosomal DNA polymorphism using frequently cutting restriction endonucleases also was found to be useful, but technically demanding and sometimes difficult to interpret. Pulse-field gel electrophoresis (PFGE) of chromosomal DNA cut with infrequent cutters supplanted the earlier molecular typing methods, and has been found to generally be reliable (De and Harrison, 1999; Riffard et al., 1998b; Gautom, 1997; Lück et al., 1995b). Other molecular methods that have been used for this purpose include ribotyping, repetitive element polymerase chain reaction (PCR), and infrequent-restriction site PCR (Fry and Harrison, 1998; Stout et al., 1988; Saunders et al., 1990; Tram et al., 1990; Van Belkum et al., 1993; Pruckler et al., 1995b; Grattard et al., 1996; Van Belkum et al., 1996; Bansal and McDonell, 1997; Miyamoto et al., 1997; Riffard et al., 1998b; De and Harrison, 1999). The two most promising methods appear to be random arbitrarily primed PCR and amplified fragment length polymorphism (AFLP). The AFLP method appears to be the most reproducible, and with proper standardization, this method might be used as a standard typing scheme (Jonas et al., 2000).

General Description of the Genus

The Legionellaceae are mesophilic, assaccharolytic, obligately aerobic Gram-negative bacilli. Amino acids rather than carbohydrates are used as an energy source. *Legionella pneumophila*, *L. micdadei*, and probably many other, if not all, *Legionella* spp. are facultative parasites of many eukaryotic cells, including some free-living

amoebae. The bacterial length is highly variable, depending upon growth conditions, stage of growth, and whether the bacterium is grown in eukaryotic cells or extracellular environments. When grown on solid media the bacterium is usually a rod 5–40 µm in length, with a cell width of 0.3–0.9 µm; bacteria incubated on plates for many days may become shorter and motile. When grown to early log phase in broth, the bacterium is usually 5–10 µm in length and single-celled, but some may be filamentous. When grown to late stationary phase ($OD_{600} > 1.8$) in broth many of the bacteria become coccobacillary and highly motile, whereas some forms are filamentous (Pine et al., 1979; Byrne and Swanson, 1998). Bacteria grown in amoebae, macrophages, or macrophage-like cell lines are short coccobacilli. All are weakly catalase-positive. The oxidase reaction is usually weak and may be negative. They are nonsporeforming and unencapsulated. All but a few species are motile by means of one to three polar or lateral flagellae, although motility may be lost. L-Cysteine is required for growth, and iron is required for initial isolation from the environment or clinical specimens; iron-free cultivation of multiple-passage isolates has been reported. The pH and temperature optima for in vitro growth are 6.8–7.0 and 25–42°C, respectively, with optimal growth occurring in vitro between 35 and 37°C. The growth optimum in nature is unknown, but may have a very wide range (10°–45°C). Branched chain fatty acids are the predominant cellular fatty acids. Cellular ubiquinones contain 9–14 isoprene units.

The G+C content of the *Legionella* genus is 38–52 mol%. The size of the *L. pneumophila* genome is approximately 3.9 Mb (Bender et al., 1990). Methods are available for constructing a genetic map of the *Legionella* chromosome (Mintz and Zou, 1992a), and current efforts are in determining [the entire sequence of the *L. pneumophila* strain Philadelphia-1 genome. Among the three means of bacterial genetic exchange, conjugation and transformation are known to function within the *Legionella* genus (Chen et al., 1984; Dreyfus and Iglewski, 1985; Segal et al., 1998b; Stone and Abu Kwaik, 1999a; Vogel et al., 1998). Thus far, there have been no reports of transduction or bacteriophage in the legionellae. Factors known to influence DNA exchange between legionellae are restriction endonucleases (e.g., *LpnI*), Dam-methylation, and RecA (Chen et al., 1986; Hamablet et al., 1989; Lema and Brown, 1996; Zhao and Dreyfus, 1990). Plasmids have been detected in some strains of *Legionella*, including representatives of *L. pneumophila* and at least five other species

(Aye et al., 1981; Brown et al., 1982; Castellani Pastoris et al., 1987; Johnson and Schalla, 1982; Lopez de Felipe and Martinez-Suarez, 1991; Maher et al., 1983; Mansfield et al., 1997; Mel-lado et al., 1986; Mikesell et al., 1981; Mintz et al., 1992c; Nolte et al., 1984; Tompkins et al., 1987). The *Legionella* plasmids occur in clinical and environmental isolates, encompass multiple incompatible groups, and range in size from 21–95 MDa. Some *L. pneumophila* plasmids are either self-transmissible or mobilizable upon bacterial conjugation (Lopez de Felipe, 1993; Mintz et al., 1992c; Tully, 1991). Although a 36-MDa *L. pneumophila* plasmid confers resistance to ultraviolet light, the majority of *Legionella* extrachromosomal elements have not been directly linked to any particular function, including aspects of intracellular infection (Mintz et al., 1992c; Tully, 1991).

Taxonomy

The genus *Legionella* was initially defined by Brenner and colleagues who examined several isolates of the newly discovered Legionnaires' disease bacillus and concluded that they represented a new family, genus and species (Brenner et al., 1979). Since then, the genus has been redefined twice to take into account the ever-increasing number of species and subspecies. Oligonucleotide cataloging of *Legionella* 16S rRNA has demonstrated that the legionellae are not closely related to other groups of organisms, but are closely related to each other at the ribosomal level (Ludwig and Stackebrandt, 1983; Fry et al., 1991). They are classified within the γ -subdivision of the Proteobacteria, within the "[Legionellaceae group]" (Ludwig and Stackebrandt, 1983).

The *Coxiella* group is included in the Legionellaceae group, and includes *Coxiella* and *Rickettsiella*. The main member of the Legionellaceae group is the Legionellaceae family. In addition to *Legionella*, the Legionellaceae family contains the *Amoeba proteus* symbiotic bacterium, *Fluoribacter* (see below), *Sarcobium*, *Tatlockia*, and a large number of unclassified bacteria that are amoebal pathogens.

Forty-two *Legionella* species have been validly published (Table 1). In addition, more than {20 novel species} have been given names, and at least 10 more without names are not yet validly published (Hookey et al., 1996; Ratcliff et al., 1997; 1998; LoPresti et al., 1998b; Riffard et al., 1998a; Benson et al., 1989; 1990; 1991; 1996a; 1996b; Dennis et al., 1993; Thacker et al., 1988a; 1989; 1991; 1992; Verma et al., 1992; Wilkinson et al., 1987b; 1988; Brenner, 1986; 1987; Bercovier et al., 1986; Brenner et al., 1979;

1980; 1985; Gorman et al., 1985; Campbell et al., 1984; Orrison et al., 1983; Cherry et al., 1982; Edelstein et al., 1982b; McKinney et al., 1981; Hébert et al., 1980a; 1980b; Morris et al., 1980). Twenty *Legionella* spp. have been reported to cause human pneumonia, with the remainder having been isolated only from water sources (Tables 1 and 2). All of the *Legionella* species that have been isolated from clinical sources also have been isolated from the environment, with the exceptions of *L. hackeliae* and *L. tucsonensis*.

Several *Legionella* spp. are apparent endosymbionts of amoebae. So far most of these have not been cultured outside of their protozoal host, making their characterization difficult. These include *Legionella lytica* (also called "*L. lyticum*"), previously known as *Sarcobium lyticum*, and a number of unnamed species known generically as "LLAP" (*Legionella*-like amoebal pathogen; Hookey et al., 1996; Adeleke et al., 1996). A recent taxonomic study indicated that there are at least three distinct *Legionella* spp. among the LLAPs (Birtles et al., 1996). Unpublished work suggests {species names} for such organisms.

Alternative Genus Names

A small number of investigators have proposed alternative genera for some of the *Legionella* species. Garrity and Brown suggested that *L. micdadei* be renamed *Tatlockia micdadei*, and that *L. bozemanii* be renamed *Fluoribacter bozemanii* (Garrity et al., 1980; 1982; Brown et al., 1981). In addition, they suggested that other blue-white autofluorescent *Legionella* species be placed into the *Fluoribacter* genus, which at the time included *L. dumoffii* (*F. dumoffii*), and *L. gormanii* (*F. gormanii*). These suggestions were based on the less than 25% DNA homology (determined by DNA-DNA hybridization) between these different *Legionella* species and *L. pneumophila*. In addition, the same group suggested that some members of *L. pneumophila* serogroup 5 be placed into a new, unnamed species, based on low homology to other members of serogroup 5 (Garrity et al., 1982).

Using multilocus enzyme electrophoresis, Selander and colleagues found multiple distinct clones within a large collection of *L. pneumophila* isolates; two of these were distant enough from the others to warrant possible classification as novel *Legionella* species (Selander et al., 1985). Brenner and colleagues (Brenner et al., 1988) confirmed that these two clones were distinct, forming two distinct DNA hybridization groups. Although highly related (88–98%) to each other, these groups were only distantly related (40–50% under stringent conditions) to

^aIsolates from humans have also been reported

L. pneumophila, with which most isolates share common antigens. Because these organisms can only be differentiated from each other in most cases by DNA hybridization studies rather than phenotypic testing, it was proposed that the species *L. pneumophila* be divided into three subspecies: *L. pneumophila* subsp. *pneumophila*, *L. pneumophila* subsp. *fraseri* and *L. pneumophila* subsp. *pascullei*. Neither the creation of the subspecies nor the use of genera other than *Legionella* has been widely adopted. Most authorities now accept the use of a single genus, and no subspecies within *L. pneumophila*. Some

bacterial strains deposited in culture collections, or nucleic acid sequences deposited in GenBank use these epithets.

Culture Media

Legionella pneumophila grows best on rich media containing yeast extract, L-cysteine, iron and organic buffers. Buffered charcoal yeast extract medium supplemented with α -ketoglutarate (BCYE α) is the primary culture medium used by most clinical laboratories. The medium pH must be 6.80–6.90, and the buffer

can be either 3-[N-morpholino] propane-sulfonic acid (MOPS) or N-(2-acetamido)-2-aminoethanesulfonic acid (ACES) although MOPS is more stable for optimal growth of the organism (Edelstein and Edelstein, 1993c). The α -ketoglutarate, is a growth stimulant (Pine et al., 1986), and is used in the BCYE medium of almost all clinical microbiology laboratories, but some research investigators omit it. The charcoal inactivates toxic peroxides produced during autoclaving of the yeast extract (Hoffman et al., 1983), and toxic compounds present in agar (Rogers et al., 1993). Alternatively, the yeast extract can be filter sterilized, facilitating the production of a clear solid medium made without charcoal, although such media do not support growth as well as does BCYE α (Edelstein et al., 1982c). The BCYE α medium can be made selective for *L. pneumophila* by the addition of cephamandole (4 mg/liter), polymyxin B (80,000 U/liter) and anisomycin (80 mg/liter); this medium is known as "BMPA" or "PAC" medium (Edelstein, 1981). Substituting the

antifungal agent natamycin for the very expensive anisomycin is more economical (Edelstein and Edelstein, 1996). Another potential antifungal agent is fluconazole (Lin et al., 1999). Because some *Legionella* spp. may be sensitive to β -lactam drugs, the substitution of vancomycin for cephamandole is used to make another selective medium, called "PAV"; the addition of glycine to this medium inhibits many environmental bacteria, and is known as "modified Wadowsky Yee" (MWY) medium (Wadowsky and Yee, 1981; Edelstein, 1982a). Although these nonselective and selective growth media have been optimized for the growth of *L. pneumophila*, it is quite possible that some other *Legionella* spp. will grow better on different medium formulations.

When cultured from spleen tissue, some *Legionella* spp., such as *L. micdadei*, may grow better in the presence in 1% albumin (Morrill et al., 1990); dilution of the spleen tissue removes the benefit of the albumin. Some research investigators also include albumin in their medium.

A variety of broth media can be made for the growth of *L. pneumophila*. The optimal growth medium is the liquid equivalent of BCYE α medium, made without agar; this charcoal-containing broth is termed "BCYE α broth". Supporting the growth of a wide range of *Legionella* spp., BCYE α broth is far better than other broth formulations at cultivating the bacteria in the presence of inhibitors, such as spleen tissue; it also is superior to other broths for recovery of frozen *Legionella* bacteria (P. Edelstein, unpublished observation). However, the inclusion of charcoal precludes visual and spectrophotometric estimation of bacterial growth in the broth, and the charcoal also inhibits many antimicrobial agents. For this reason, BYE α broth (made by filter sterilization of the yeast extract, to which the other autoclaved medium components are added) is used for a variety of reasons, including antimicrobial susceptibility testing and for estimating growth of the bacterium when the charcoal is not desired (Edelstein and Edelstein, 1989b; Edelstein et al., 1989c; Ristroph et al., 1980; Barker et al., 1986). The addition of ACES (rather than MOPS) buffer to BYE α broth may enhance the virulence of *L. pneumophila* (Ross et al., 2000).

Genus and Species Identification

Identification of *Legionella* spp. to the genus level is usually quite easy, as is identification of *L. pneumophila*. This is because the combination of L-cysteine dependence, colonial morphology and growth rate is very specific for *Legionella* spp., and because a very sensitive and specific monoclonal antibody for *L. pneumophila* is available for identification. The serological method was initially used to identify isolates beyond genus level. However, it soon became apparent that many species share antigenic epitopes so that even within a species, serological identification may be misleading. Very simple to complex tests that require sophisticated analytical instruments have been developed for species level identification. Even with the use of sophisticated biochemical characterization, some species can only be identified on the basis of DNA or rRNA sequence analysis, or DNA-DNA hybridization studies. This means that only a handful of laboratories are able to identify unusual *Legionella* spp., especially novel ones.

Growth Rate and Colonial Morphology

When plated from primary clinical or environmental specimens, colonies of legionellae appear on selective or nonselective BCYE α agar within 3–14 days (average 3–4 days) of incubation. Growth from a fresh colony generally requires

18–36 h of incubation, depending on the density of the inoculum; a heavy inoculum usually grows overnight, and a light inoculum may take several days to grow on subculture. Some of the more fastidious species, such as *L. oakridgensis*, *L. sainthelensi* and *L. rubrilucens* may require up to several more days of incubation for growth to appear on subculture; these and some other *Legionella* spp. may grow better in the presence of 3–5% CO₂. Recognition and preliminary identification of the bacteria are facilitated by the use of a dissecting microscope for the examination of the media. *Legionella* colonies display a characteristic appearance resembling "ground glass," or an opal, when viewed under obliquely transmitted light. Very young colonies are gray, flat, round, entire and about 0.25–0.5 mm in diameter; at this stage they are very difficult to see with the naked eye. Within a day the colonies become raised, round, entire and convex, and are 1–2 mm in diameter. The colony edge usually displays a birefringent band, which is either greenish blue or pink depending on the species; this coloration may be pleomorphic but does not breed true. Up to this stage, the colonial morphology is distinctive for experienced observers. As the colonies become several days older, the ground-glass appearance and the birefringent edge tend to disappear and the colonies become umbonate and sometimes tuberculated; the maximum diameter is usually about 3–4 mm. Eventually the colonies flatten completely. Very old colonies are impossible to distinguish with certainty from other bacteria, even for experts. This makes it especially important to examine plates for early growth when plating from primary specimens, or when contamination with other bacteria is a possibility. When the colonies are illuminated with a Woods' lamp the colonies of most species will exhibit a dull yellow fluorescence (Table 3). The colonies of *L. bozemanii*, *L. gormanii*, *L. dumoffii* and several other species, display a very striking blue-white autofluorescence under similar conditions of illumination, whereas colonies of *L. rubrilucens*, *L. erythra* and some strains of *L. taurinensis* produce a red fluorescence.

Most *Legionella* spp. growing on BCYE α medium have a characteristic musty smell. This odor is specific enough to aid in the identification of the bacterium. Incubators containing several plates with heavy growth of *Legionella* spp. emit this odor when first opened, as do individual culture plates.

Cellular Morphology and Biochemical Characteristics

The cellular morphology of *Legionella* spp. bacteria is dependent on growth phase, both in vitro

Symbols: –, negative; +, positive; and +/-, most strains positive, or all strains weakly positive.

Abbreviations: TYE, tyrosine-containing buffered yeast-extract medium without charcoal; and NA, not applicable.

^aColony color when illuminated with long wave UV light: BW, blue-white; YG, yellow-green; NC, no distinct color; R, red; and R/yg, majority are red, some are yellow-green. This color is dependent on growth conditions and colony age, and may be lost with serial passage. “No autofluorescence” reported by some authors is signified by “NC”; it is unclear whether these colonies fluoresce a yellow-green color.

^bThese results may differ according to growth conditions and methods of analysis. The fatty acids are listed in order of predominance, with only the first two to three predominant fatty acids listed.

^cListed in order of predominance when not in numerical order; otherwise species designated as possessing multiple major ubiquinones containing them in approximately equal amounts.

^dThese strains may grow on BCYEα media made without L-cysteine, but generally only after serial passage. L-Cysteine is required for primary isolation for all of these species, and for optimal growth for some.

Data compiled from original published descriptions of the species, from unpublished data (P. Edelstein), and from Gilbert (1985).

and in vivo. The bacterium can vary from highly motile tiny (1 μm) coccoid forms during the last stages of intra-amoebal growth to very long and nonmotile filaments (2–3 × 20 μm) during stationary phase on solid media. Bacteria grown to

early log phase are nonmotile short bacilli, in broth, on solid media, and in the early stages of intra-amoebal and intra-macrophage growth. In late stationary phase on solid media, and in broth, there can be a mixture of filamentous

forms, medium-length rods, and short motile coccoid forms (Rowbotham, 1986; Anand et al., 1983; Byrne and Swanson, 1998; Pine et al., 1979).

Ultrastructural studies of the bacteria show an arrangement characteristic of Gram-negative rods, with typical trilaminar inner and outer membranes (Chandler et al., 1979b; Neblett et al., 1979; Rodgers, 1979; Watson and Sun, 1981; Rodgers and Davey, 1982). A definite peptidoglycan structure also is seen in the cell wall (Flesher et al., 1979; Rodgers and Davey, 1982). *Legionella micdadei* has a unique electron dense layer in the periplasmic space that is not seen in *L. pneumophila* (Gress et al., 1980; Hébert et al., 1984). Several species, except *L. micdadei*, appear to have an extracellular polysaccharide capsule or slime layer that can be visualized by ruthenium red staining, even though the bacteria appear unencapsulated by other means (Hébert et al., 1984). Both flagellae and pili have been observed in some ultrastructure studies (Chandler et al., 1980; Rodgers et al., 1980b).

Staining characteristics depend to some degree on the source of the bacteria. Typically, Gram stain does not reliably stain the legionellae in clinical specimens, although bacteria cells from artificial media stain somewhat better. The substitution of basic fuchsin for the safranin counterstain in the Gram technique makes the legionellae more readily visible. Staining of the legionellae can also be accomplished using crystal violet and methylene blue, although these methods are not currently used (de Freitas et al., 1979; Pasculle et al., 1980). *Legionella micdadei* is unusual in that the cells are weakly acid fast when present in tissue but readily lose this property after a single passage on artificial media. The reason for this is unknown (Pasculle et al., 1980). *Legionella pneumophila* has also been reported to be positive on acid-fast staining of bronchoalveolar lavage material (Bentz et al., 2000). The legionellae can also be readily stained by the Gimenez stain (McDade et al., 1977) and the Dieterle silver (Chandler et al., 1977) stains, but neither technique is specific for these bacteria.

The legionellae are chemoorganotrophic do not possess a glucose transport system, nor do they ferment or oxidize other carbohydrates. Early studies using several defined media suggested that methionine, arginine, threonine, serine, isoleucine, leucine and valine are required by the legionellae, in addition to cysteine. Serine, glutamate and perhaps threonine appear to serve as the primary carbon and energy sources for the legionellae and are catabolized via the Krebs cycle. Carbohydrate synthesis occurs through gluconeogenesis via the Embden-Meyerhof pathway (Pine et al., 1979; George et al., 1980; Tesh and Miller, 1981; Tesh and Miller, 1983a;

Tesh et al., 1983b). α -Ketoglutaric acid is a growth stimulant and a component of most growth media for the bacterium (Pine et al., 1986; Edelstein, 1981).

Members of the genus *Legionella* cannot be identified with any degree of certainty using traditional biochemical testing. This is because of the general biochemical inertness of the bacterium when using conventional biochemical tests, and because many of the species can only be correctly identified using molecular methods. An extensive panel of biochemical tests has been shown to be useful in identification, but these methods have not been widely used or validated after their initial description, nor has their use been described with newly recognized species (Vesey et al., 1988). The tests that appear to be most useful for bacterial identification include demonstration of L-cysteine growth dependence, serotyping to detect *L. pneumophila* and *L. pneumophila* serogroup 1, determination of cellular fatty acids and ubiquinones, and determination of the macrophage infectivity potentiator (mip) gene sequence (Ratcliff et al., 1998). The few phenotypic tests that can be used to separate these organisms into groups are given in Table 3. All species are motile via one to three polar or subpolar flagella and the flagella of all legionella species appear to be antigenically identical (Bornstein et al., 1991). Only *L. oakridgensis* appears to be nonmotile. Determination of flagellation may be difficult as flagellar production is growth-condition dependent (Heuner et al., 1999). It is much easier to demonstrate flagellae in plate-grown than broth-grown bacteria, especially from plates that have been incubated at room temperature. The Ryu stain is a convenient method for staining the flagellae (Kodaka et al., 1982; Edelstein, 1985b). Tests for nitrate reductase and urease are negative for all species. Most strains are reported to be catalase positive when whole cells are tested for the ability to decompose hydrogen peroxide (H_2O_2); the catalase reaction can be very weak. Methods that enhance the sensitivity of the catalase reaction include performance of the test using capillary tubes and the use of 3% H_2O_2 in 10% Tween 80 (Edelstein, 1985b). Studies using cell-free extracts, however, have demonstrated the *L. pneumophila* and *L. gormanii* have only peroxidase activity, whereas other *Legionella* species in actuality do possess catalase (Pine et al., 1984). Most species liquefy gelatin, using an assay medium in which gelatin replaces agar in the formulation of BCYE α medium (Edelstein, 1985b). *Legionella pneumophila* and a few other species hydrolyze hippurate (Edelstein, 1985b). Most strains produce a β -lactamase that is active against cephalosporins and can readily be demonstrated using nitrocefin (Marre et al., 1982).

Browning of tyrosine-containing medium is also a helpful phenotypic test, using BCYE α medium made without charcoal and containing tyrosine (Edelstein, 1985b).

Cellular Lipids, Quinones and Carbohydrates

The cell wall of the legionellae contains large amounts of branched-chain fatty acids and only minor amounts of hydroxy acids (Mayberry, 1981; Lambert and Moss, 1989; Table 3). Accurate cellular fatty acid composition determination requires the use of a high quality gas liquid chromatograph and capillary columns, and also may require the use of mass spectroscopy. Fatty acid characterization is too complex to be used in the routine identification of *Legionella* spp. isolates, but can be of great help to taxonomists, or to identify unusual isolates. Analyses for very long chain fatty acids and unusual lipopolysaccharides also can be used to help identify some *Legionella* spp. (Moll et al., 1992; Sonesson and Jantzen, 1992; Sonesson et al., 1989; 1993; 1994a; 1994b; 1994c; Jantzen et al., 1993). Characterization of complex cellular sugars also can be used to characterize and identify some *Legionella* spp. (Fox et al., 1990). The instrumentation for fatty acid and polysaccharide analysis is very expensive and difficult to maintain, and requires a high level of technical expertise for its use. In addition, extraction of the fatty acids is labor intensive and utilizes hazardous chemicals, although a relatively rapid technique has been described (Nalik et al., 1992).

The legionellae also are unusual in that their isoprenoid quinones are ubiquinones with side chains containing greater than nine isoprenoid units (Karr et al., 1982; Moss and Guerrant, 1983; Marmet et al., 1988; Lambert and Moss, 1989). The determination of fatty acid and ubiquinone profiles is generally too complex for routine laboratory use. These procedures are, however, very helpful in the preliminary characterization of isolates by reference laboratories.

Identification Techniques

L-Cysteine Growth Dependence

Establishing the L-cysteine growth dependence (characteristic of the genus *Legionella*; Benson and Fields, 1998) is usually the first step for a Gram-negative bacterium growing on BCYE α medium with colonial morphology typical of *Legionella* spp. In most laboratories, this is done by inoculating the isolate onto a cysteine-deficient BCYE α agar plate (Isenberg, 1979).

Other cysteine-deficient media (such as sheep blood agar) may be used for this purpose, but occasional strains of other heterotrophic environmental bacteria may be encountered that will grow on BCYE α and not on blood agar (Thacker et al., 1981). Placement of an L-cysteine-containing disk on cysteine-deficient BCYE α , or on tryptic soy blood agar, will result in growth of the *Legionella* bacteria around the disk (Smith, 1982). In addition, *Brucella* blood agar will support the growth of at least some *Legionella* bacteria, as will several other rich media (P. Edelstein, unpublished observation). After serial passage, several *Legionella* species can grow on media without L-cysteine, but generally still exhibit L-cysteine dependence on the first or second passage on artificial media (Table 3).

Serotyping

Several of the various recognized species and serovars of *Legionella* can be identified by serological methods. Fluorescein-conjugated antisera for direct immunofluorescence testing can be used for the rapid presumptive identification of isolates (Cherry et al., 1978; Wilkinson, 1987a; Edelstein and Edelstein, 1989a). Because *L. pneumophila*, and especially *L. pneumophila* serogroup 1, accounts for the preponderance of clinical isolates (Reingold et al., 1984; Dournon et al., 1985; Marston et al., 1994), most clinical isolates can be identified using commercially available antisera to *L. pneumophila* serogroup 1, and to *L. pneumophila*. A monoclonal antibody conjugate that reacts with all known serogroups of *L. pneumophila* is commercially available (<http://www.biorad.com> [Biorad] [formerly Genetic Systems] Hercules, CA; Edelstein et al., 1985d; Tenover et al., 1986; Gosting et al., 1984). Several firms make *L. pneumophila* serogroup 1 specific antibodies, as well as antibodies for a number of other species and serogroups m-TECH (<http://www.4m-tech.com>); MarDx, now Trinity Biotech (<http://www.trinitybiotech.com/prod.htm>); Scimedex (<http://www.globaldx.com/products.html>).

Tests need to be interpreted with caution. A prozone phenomenon can cause a false-negative reaction if the bacterial suspension being tested is too heavy. In addition, the monoclonal antibody reacts with a bacterial antigen that is hidden by prolonged Formalin fixation (Gosting et al., 1984), making adherence to the manufacturer's guidelines important.

Simple slide agglutination tests for the identification of the legionellae are also commercially available, although their performance characteristics have not been described Oxoid (<http://www.oxoidshop.com>); Mast (<http://www.mastgrp.com/intro.htm>).

Extensive crossreactions among the legionellae requires that the polyclonal antisera used for this procedure and for immunofluorescence be subjected to reciprocal adsorption to remove crossreacting antibodies. Such cross-absorbed antisera are not commercially available, making most identification by serotyping subject to error. The monoclonal antibody to *L. pneumophila* does not crossreact with other *Legionella* spp, nor does the polyclonal antibody to *L. pneumophila* serogroup 1. However, there are several *L. pneumophila* serovars that share antigens with different serogroups, such as *L. pneumophila* "serogroup 1,4" and *L. pneumophila* "serogroup 1,5." Within *L. pneumophila* serogroup 1, there may be a wide range of reactivity between antisera made to the Philadelphia 1 and Bellingham strains, such that antibodies to one of these two polar serovars may not react with the other serovar. Several novel *Legionella* species have been identified that react with antibody to other species, making molecular identification crucial for definitive identification.

Molecular Methods for Species Identification

DNA-DNA hybridization at different temperatures is the definitive means of identifying currently recognized *Legionella* spp., and of differentiating them from novel species (Brenner et al., 1979; Brenner, 1987; Benson and Fields, 1998). A commercial test kit, manufactured and sold in Japan (Kyokuto Seiyaku Co; "DDH-Legionella"), takes advantage of this technology; no published evaluations of the performance of the kit are available. Evaluations of a research kit showed excellent performance (Ezaki et al., 1990; Hatanaka et al., 1992), and evaluation of the underlying methodology shows excellent correspondence with the standard method (Goris et al., 1998). The most promising new method appears to be sequencing of the *mip* gene, using degenerate primers, as this can be accomplished by laboratories with access to thermal cyclers and automated sequencing instruments (Ratcliff et al., 1997; 1998). Other methods that have been tested include 16S and 5S rRNA sequencing, as well as random amplified polymorphic DNA analysis (RAPD; Ludwig and Stackebrandt, 1983; MacDonell and Colwell, 1987; Böttger, 1989; Fry et al., 1991; Hookey et al., 1996; Robinson et al., 1996; Pinar et al., 1997; Riffard et al., 1998a; Bansal and McDonell, 1997; LoPresti et al., 1998b). Sequencing of 5S rRNA appears to be unable to discriminate between all species (Murdoch et al., 1999b), whereas sequencing of 16S rRNA may be more discriminatory (Riffard et al., 1998a; Benson and Fields,

1998). A thorough comparison of the use of RAPD versus that of other molecular techniques has not been reported.

Laboratory Diagnosis

Nonspecific Findings

A number of nonspecific laboratory abnormalities may occur in Legionnaires' disease. These are abnormal urinalysis with proteinuria and hyaline or granular casts; hypophosphatemia, hyponatremia, and less commonly, elevations of aldolase or creatine kinase (Arrizabalaga et al., 1984; Cheung, 1980; Heule et al., 1986; Tsai et al., 1979). Extreme electrolyte abnormalities related to massive diarrhea occur rarely (Foltzer and Reese, 1985). Renal failure has been reported rarely. The renal failure may occur with myositis and/or marked elevations of creatine kinase and aldolase or with myoglobinuria and may represent rhabdomyolysis (Lin et al., 1995; Cases et al., 1987; Fenves, 1985; Hall et al., 1983; Poulter et al., 1981; Harvey et al., 1980; Williams et al., 1980). In addition, interstitial nephritis, mesangial proliferative and progressive glomerulonephritis all have been reported (Pai et al., 1996; Hariparsad et al., 1985; Wegmüller et al., 1985). The white blood cell count is elevated ($>10,000/\mu\text{l}$), often with a left shift in about one-half to three-fourths of patients. Leukopenia and thrombocytopenia are observed in severe disease. Serum cold agglutinins and even cold agglutinin disease also have been observed in several cases (King and May, 1980). Disseminated intravascular coagulation is observed rarely, usually in the setting of severe respiratory failure and diffuse lung infiltrates (Dowling et al., 1983; Gregory et al., 1979). Elevations of lactic dehydrogenase, alkaline phosphatase and aspartate aminotransferase are also common (Kirby et al., 1980; Cunha, 1987). Bilirubin elevation is less common, but there are several case reports of jaundice as a presenting sign of illness, as well as severe jaundice occurring as part of the disease (Verneau et al., 1987; García et al., 1991; Levin et al., 1993). Hypoxemia is usually in proportion to the degree of pulmonary involvement seen on radiographs (Kirby et al., 1980; Cunha, 1987). None of the nonspecific laboratory findings predicts with reasonable certainty whether a patient has Legionnaires' disease or another cause of pneumonia (Edelstein, 1993a; Fang et al., 1990a).

Specific Findings

There are four currently used standardized methods for the specific laboratory diagnosis of

Legionella infections (Table 2). These are determination of antibody level, demonstration of the bacterium in tissues or body fluids by using immunofluorescent microscopy, actual isolation of the organism on culture media, and detection of antigenuria (Aguero-Rosenfeld and Edelstein, 1988; Edelstein, 1987a; Plouffe et al., 1995; Ramirez and Summersgill, 1994; Birtles et al., 1990). Detection of bacterial DNA using PCR is being used experimentally, but has yet to be widely adopted (Helbig et al., 1999; Murdoch et al., 1996; Murdoch et al., 1999a; Weir et al., 1998; Koide and Saito, 1995; Maiwald et al., 1995; Jaulhac et al., 1992; Jaulhac et al., 1998). A commercial DNA probe test used to diagnose *L. pneumophila* rRNA is no longer being produced (Edelstein et al., 1987c; Doebbeling et al., 1988; Pasculle et al., 1989).

Antibody Estimation

Estimation of serum antibody to *L. pneumophila* is a commonly used means of diagnosing Legionnaires' disease (Edelstein, 1997). The vast majority of laboratories use an indirect immunofluorescent microscopy (IFA) technique to determine antibody concentrations. Only measurement of antibody to *L. pneumophila* serogroup 1 by IFA is well standardized, and is the "gold standard" test used to diagnose Legionnaires' disease by serologic means. Several commercial enzyme immunoassays (ELISA) can be successfully used to screen antibodies for elevated levels, which can then be confirmed with the *L. pneumophila* serogroup 1 IFA (Harrison et al., 1999).

There are two widely used reference methods of antigen preparation for the IFA test: heat fixation of plate-grown bacteria and formalin fixation of chicken embryo yolk-sac grown bacteria (Edelstein, 1997). The latter method may be more specific although large head-to-head comparative studies have not been performed (Harrison and Taylor, 1982). Many commercial laboratories sell kits containing Formalin-fixed plate-grown bacteria, but these kits are not known to provide the same results as either of the reference methods. Use and results interpretation of these commercial IFA kits may not give results similar to those obtained using the reference methods.

About three-quarters of patients with culture-proven Legionnaires' disease caused by *L. pneumophila* serogroup 1 develop a fourfold rise in IFA titer from one to nine weeks after onset of illness. The mean time required for demonstration of seroconversion is about two weeks; however, up to 25% of seroconversions are missed unless serum is collected up to eight weeks after onset of illness. Because 5–30% of healthy pop-

ulations sampled have *L. pneumophila* serogroup 1 antibody titers of 1 : 128 or greater when using a heat-fixed antigen, only a fourfold rise in titer to 1 : 128 or greater can be considered significant; significant titers for formalin-fixed antigen are a rise in titer to 1 : 32 or greater. In the face of an outbreak of Legionnaires' disease, a single titer of >1 : 256 (heat-fixed antigen) in a patient with a compatible clinical illness has been considered significant. However, in the sporadic case such single high titers cannot be interpreted (Plouffe et al., 1995). The specificity of the IFA test in a hospitalized population is not well known; this probably approximates 90% for a fourfold titer rise, although in an epidemic situation in nonhospitalized patients the specificity is close to 100%.

Crossreactions for the IFA test have been reported in patients with tuberculosis, pneumococcal pneumonia, pseudomonas pneumonia, exacerbations of cystic fibrosis, tularemia, plague, *Bacteroides fragilis* bacteremia, and leptospirosis (Bornstein et al., 1987; Edelstein et al., 1980a). Up to 20% of patients with campylobacter enteritis have been reported to have crossreactive antibody to *L. pneumophila* (Boswell, 1996; Marshall et al., 1994; Boswell and Kudesia, 1992). Antibody testing is most specific when using *L. pneumophila* serogroup 1 antigen, especially when a Formalin-fixed antigen is used. The specificity of a fourfold antibody rise to the serogroup 1 antigen is at least 99%, whereas test specificity is considerably lower when using antigens from other *L. pneumophila* serogroups, or from other species. Aside from variability in antibody test results due to the type and numbers of antigens tested, other methodologic variables may affect results. None of the commercially available kits for IFA determination of antibody status use exactly the same methods that were used for determination of test performance. In addition there has never been conducted a valid study of the clinical specificity and sensitivity of IFA kits using multiple antigens, or antigens other than *L. pneumophila* serogroup 1. Thus it is improper to use cutoff values determined for *L. pneumophila* serogroup 1 antibodies when interpreting the meaning of antibodies to other antigens. Because of this, it is better not to test for antibody to antigens other than *L. pneumophila* serogroup 1, except for epidemiological studies. In addition to the possibility of crossreactions and the fact that serologic testing is retrospective in nature (and does not influence choice of therapy), the other major drawback of diagnosing *Legionella* infections using serologic means is that the test may be negative because the serotype of the infecting organism is not tested for. Thus, serologic testing in the diagnosis of this disease is much more helpful to epidemi-

ologists than to clinicians caring for individual patients.

Several EIA kits that measure *L. pneumophila* antibodies are commercially available, and are manufactured or sold in the United States by Wampole Laboratories, Zeus Diagnostics, and Sigma Diagnostics. The Sigma kit is made by Zeus Diagnostics and is essentially the same kit. Unfortunately there is only one published evaluation of some of these kits (Harrison et al., 1999), and one publication describing the performance of a commercial kit that is not widely available (Nguyen et al., 1995). All of these kits screen for IgA, IgM and IgG antibodies to *L. pneumophila* serogroups 1 to 6. The sensitivity of the kits for measurement of antibody to *L. pneumophila* serogroups 2 to 6 is unknown, but they do appear to be reasonably sensitive (70–90%) for the estimation of serogroup 1 antibodies. Test specificities are about 98%. The tests are designed to detect relatively high IFA titer antibody, in the range of 1:128 to 1:256. Because the antigens detected are a pool of serogroups, a positive enzyme immunoassay (EIA) result can be due to cumulative low-level antibodies to different serogroups, as has been observed for the IFA assay using multiple antigens. Because of this, the positive predictive accuracy of the Wampole assay is about 90%, in other words about 90% of EIA-positive or indeterminate sera will have IFA titers (heat-killed antigen) ≥ 64 , with most >64 (P. Edelstein, unpublished data). All positive EIA tests should be confirmed by use of the IFA test using a *L. pneumophila* serogroup 1 antigen (Harrison et al., 1999). The best use of the EIA test is as a screening assay of convalescent-phase sera. Any such sera yielding positive or indeterminate results can then be tested in parallel with the acute-phase serum by IFA. Using this scheme, about 10% of serum pairs so selected are positive for a significant change in IFA titer (P. Edelstein, unpublished data).

An evaluation of the optimal characteristics for antibody detection by ELISA show that a sonicated antigen used with IgA detection was most sensitive, whereas use of a lipopolysaccharide antigen with IgG and IgM detection, was most specific (Bangsberg et al., 1994). No commercial ELISA assay utilizes LPS antigens.

Detection of Bacterial Antigen in Tissues

Immunofluorescent microscopy of respiratory tract secretions, lung and pleural fluid is one of the rapid test methods available to establish a laboratory diagnosis of Legionnaires' disease. When this technique is used with an antibody conjugated with a fluorochrome, it is termed the "direct immunofluorescence assay" (DFA). About 2–3 hours is required to complete this

test. This technique has been used very successfully with expectorated sputum, endotracheal suction aspirates, lung biopsies and transtracheal aspirates. Use of secretions or biopsies obtained by bronchoscopy has not resulted in high yield in our experience, although others have had more success. Pleural fluid examination in patients with Legionnaires' disease usually is unproductive, both in terms of culture and DFA positivity, but it has occasionally been helpful. The true sensitivity of the DFA test is unknown. About 25–70% of patients with culture-proven Legionnaires' disease have positive sputum DFA tests for *L. pneumophila*; test specificity is greater than 99.9%; therefore, a negative result does not rule out disease and a positive result is almost always diagnostic of it (Edelstein et al., 1980b). Antisera used to detect infection caused by *L. pneumophila*, especially *L. pneumophila* serogroups 1 to 4, are more specific than other antisera; use of antibodies other than these is problematic because of crossreactions, and should be confined to testing normally sterile tissues and fluids (e.g., lung biopsies), if at all possible. A commercially available (from <http://www.biorad.com> {Biorad} [formerly Genetic Systems], Hercules, CA) monoclonal antibody DFA reagent which reacts with all serogroups of *L. pneumophila* provides optimal specificity and eliminates the need to use multiple antisera to detect this species (Edelstein et al., 1985d; Tenover et al., 1986). Unlike polyvalent reagents, it does not crossreact with some *Pseudomonas*, *Flavobacterium-Xanthomonas* and *Bacteroides* strains; however it cannot be used to stain tissues fixed in formalin for prolonged periods. When sera other than the monoclonal antiserum are used, it is wise to interpret with extreme caution positive smears of tissues or fluids that might contain large quantities of known crossreacting bacteria. Exceptional skill is needed to read DFA test slides properly. DFA tests of sputum remain positive for 2–4 days after the initiation of specific antibiotic therapy for Legionnaires' disease, and often much longer in cases of cavitary pulmonary disease.

Culture Isolation from Clinical Specimens

Isolation of *Legionella* from clinical specimens is routinely performed in many laboratories. The medium used, supplemented charcoal yeast extract medium (BCYE α), is easily prepared by any large clinical microbiology laboratory and can be made in a selective form. Use of selective media and specimen decontamination with acid are obligatory for optimal culture yield from normally nonsterile tissues and fluids. To obtain optimal yield, specimens with and without acid pretreatment are plated on three different media

(all commercially available; total of six plates): BCYE α (nonselective), BMPA (selective, also called "CAP" or "PAC"), and MYEA (selective, also called "PAV" or "VAP"; Edelstein, 1985a; 1985b; 1987a; Vickers et al., 1987). Use of two different selective media is required as some *Legionella* spp., and some strains of *L. pneumophila* serogroup 1, will not grow on BMPA, which is the most selective medium. Use of multiple media also increases the chances of detecting very small numbers of *Legionella* spp. bacteria present in the specimen. Specimen dilution before plating is also important, as *Legionella* spp. growth may be inhibited by certain cations, other bacteria and by tissue factors. The organism has been successfully isolated from sputum, transtracheal aspirates, endotracheal suction specimens, blood, lung biopsy, pleural fluid, bronchial lavage, pericardial fluid, peritoneal fluid, wounds, bowel abscesses, prosthetic heart valves, brain abscesses, myocardium, kidney, liver, vascular grafts and respiratory sinuses. Cultures generally remain positive for several days after the initiation of antimicrobial therapy, and may remain positive for weeks or months from pulmonary abscesses. Broad-spectrum antimicrobial therapy decreases culture yield.

Like the sensitivity of all other tests for Legionnaires' disease, that of culture is unknown. Nevertheless, it is often more sensitive than other available diagnostic tests. Only about 75% of people with culture-proven Legionnaires' disease develop antibody conversion; less than half have positive sputum DFAs; and a large, although poorly defined, fraction of all those without *L. pneumophila* serogroup 1 infections have negative urinary antigen tests. However, it is common in community-based outbreaks of Legionnaires' disease for sputum cultures to be negative, while urinary antigen tests, and somewhat less commonly, serum antibody tests are positive. It is unclear how often the negative sputum cultures in this situation are due to inexpert laboratory testing, improper or inadequate sputum collection, or both. It is likely that urinary antigen testing is the most sensitive test for Legionnaires' disease in patients with *L. pneumophila* serogroup 1 disease.

Once isolated on a culture medium, *Legionella* spp. are relatively easy to identify to the genus level. This is based on characteristic colonial morphology, growth requirement for L-cysteine, and serotyping. Also helpful are characteristic branched-chain cellular fatty acid and ubiquinone compositions, and lack of acid production from carbohydrates. Because of the antigenic complexity of Legionellae, it is impossible to serologically distinguish several of the species. Combined with a paucity of other useful phenotypic characteristics, this means that identifica-

tion to the species level can be very difficult, except for extremely sophisticated research laboratories. However, all laboratories should be able to identify *L. pneumophila*, *L. pneumophila* serogroup 1, and other Legionellae to the genus level. This is because of the availability of a *L. pneumophila* species-specific monoclonal antibody (Genetic Systems), of many available and reliable *L. pneumophila* serogroup 1 polyclonal antibodies, and because of the specificity of colonial morphology, Gram stain appearance, and L-cysteine dependence for all *Legionella* species (see Table 3 for exceptions).

Microscopic morphology of the organisms depends on growth conditions. They are usually very faintly staining small coccobacilli in lung and sputum, and often long and filamentous bacilli when taken from a culture plate. Although colonies growing on artificial media stain well with Gram stain (especially if basic fuchsin rather than safranin is used as the counterstain), the bacteria are exceptionally difficult to visualize using this stain on fixed lung specimens, and often with fresh tissues and fluids also. For tissue examination, the Giménez stain is more effective, much simpler and more sensitive than the Dieterle silver impregnation stain (Edelstein et al., 1980b).

Polymerase Chain Reaction

Although PCR has been used to diagnose Legionnaires' disease, this test is still regarded as a research tool. In most studies the sensitivity of PCR has been lower than that of culture. *Legionella* spp. DNA has been successfully detected with PCR in human and experimental animal urine, although the urine PCR may not be as sensitive as the urine antigen test. Urine PCR may be useful for detecting *L. pneumophila* serogroups and species not detected by the antigen test (Helbig et al., 1999; Murdoch et al., 1996; Murdoch et al., 1999a; Weir et al., 1998; Koide and Saito, 1995; Maiwald et al., 1995; Jaulhac et al., 1992; Jaulhac et al., 1998).

Antigenuria

Legionella pneumophila serogroup 1 antigenuria can be detected by using an enzyme immunoassay or radioimmunoassay (Tilton, 1979; Kohler et al., 1981; 1984; Sathapatayavongs et al., 1982). There are several commercial enzyme immunoassay kits available; the best studied one is made by the Binax Company, and was formerly made by Dupont (Aguero-Rosenfeld and Edelstein, 1988; Plouffe et al., 1995; Hackman et al., 1996; Kazandjian et al., 1997; Domínguez et al., 1998). It is now made by Binax and sold by (<http://www.wampolelabs.com/>

in_fp_Legionella.htm{Wampole Labs}, Cranbury, NJ).

The sensitivity of the Binax/Wampole assay is quite high; more than 95% of urines collected from patients with culture-proven *L. pneumophila* serogroup 1 disease are positive with the test. About 80% of urines collected with patients with only serologically proven Legionnaires' disease are positive in the assay; inasmuch as some of these patients may have had infection caused by other *L. pneumophila* serogroups, other *Legionella* spp., or may not have had Legionnaires' disease (but only a false-positive antibody test), the sensitivity of the assay is probably higher than 80% (Kohler, 1986). The clinical sensitivity yield of urinary antigen testing has uniformly been much higher than culture in outbreaks of Legionnaires' disease, and use of this test is essential when investigating epidemics of *L. pneumophila* serogroup 1 pneumonia (Jernigan et al., 1996; Brown et al., 1999; Fiore et al., 1998). In sporadic cases of community-acquired Legionnaires' disease, the sensitivity of antigenuria detection of *L. pneumophila* can also be higher than that of sputum culture, even when excellent culture techniques are used (P. Edelstein, unpublished observation); in laboratories not utilizing optimal culture techniques the disparity in diagnostic yield for the two test types can be dramatic. Patients with severe Legionnaires' disease, such as those with respiratory failure and multilobar pneumonia, may excrete bacterial antigen in their urine for weeks to months after recovery from pneumonia; this phenomenon does not occur in patients with mild Legionnaires' disease (Kohler et al., 1984). Test sensitivity can be enhanced by urine concentration before testing (Domínguez et al., 1996; 1997).

The Binax/Wampole assay is largely specific for *L. pneumophila* serogroup 1 and has low sensitivity for detection of antigenuria caused by infections with other *L. pneumophila* serogroups or other *Legionella* spp. Some crossreactions do occur, so a positive urinary antigen test does not exclude infection caused by other *L. pneumophila* serogroups (Kohler et al., 1985). Crossreactions can be demonstrated with a number of *L. pneumophila* serogroups using culture extracts (Domínguez et al., 1998). False-positive tests are often associated with rheumatoid-like factors, which can be eliminated by boiling the sample before testing; the *Legionella* antigen itself is heat stable (Kohler et al., 1981). In addition, cloudy urines rarely produce false-positive tests, although when they do, the false positivity can be eliminated by pre-test centrifugation.

The Biotest urinary antigen detection assay (<http://www.biotest.com>{Biotest AG}, Dreieich, Germany) claims reactivity with a variety of *L. pneumophila* serogroups. However, there is little

reliable clinical data to evaluate this possible difference; an in vitro study of several different *L. pneumophila* antigens showed no significant differences between the two tests (Domínguez et al., 1998). In the same study, there was no significant difference in the ability to detect *L. pneumophila* serogroup 1 antigenuria. (<http://www.intracel.com/bartels/bartels.html>{Bartels Diagnostics}) has recently introduced a *L. pneumophila* serogroup 1 antigen assay, but only abstracts and an (<http://www.fda.gov/cdrh/pdf/k991074.pdf>{FDA summary}) of evaluations are available.

Recently, urinary antigen testing has been simplified by use of an immunochromatographic card assay (<http://www.binax.com/legionella.html>{Binax, Portland, Maine}). This assay appears to be about as sensitive and specific as the ELISA tests (Domínguez et al., 1999).

Antimicrobial Susceptibility Testing

Because *Legionella* bacteria reside in human macrophages, there is a poor correlation between standard in vitro susceptibility tests and treatment efficacy. For example, several β -lactam drugs are highly active against broth grown *L. pneumophila*, but completely inactive against the intracellular bacterium, and in the treatment of Legionnaires' disease (Edelstein, 1995a). Assays of the activity of antimicrobial agents against the intracellular bacterium correlate better with clinical outcome, but may not be completely accurate. Infection of explanted guinea pig alveolar macrophages is the best-standardized model for the study of intracellular susceptibility to antimicrobial agents (Edelstein and Edelstein, 1999b). A wide variety of cell lines have been used to perform such intracellular testing, but no studies exist comparing these results to the use of the guinea pig alveolar macrophage model (Higa et al., 1998; Stout et al., 1998). Although continuous cell lines have the advantage of being readily available, their use introduces the methodologic problem of how to deal with an expanding host cell population during the course of the study and with uncertainty about antimicrobial kinetics in these cells. The best correlation between clinical effectiveness and experimental activity is with the guinea pig pneumonia model (Edelstein, 1999a).

Environmental Ecology and Microbiology

Environmental Ecology

The legionellae are ubiquitous in our natural aqueous environment. Most *Legionella* spp. have

been recovered only from water sources (Table 2). Humans are accidental hosts of these bacteria, which in nature appear to be facultative parasites of free-living amoebae. Early environmental surveys of natural bodies of water (including rivers, lakes and creeks) found *L. pneumophila* to be present in relatively high concentrations in most sites (Fliermans et al., 1979; Fliermans et al., 1981; Fliermans et al., 1983; Tyndall et al., 1983; Morris et al., 1979; Cordes et al., 1981; Cherry et al., 1982). In addition, thermally polluted water was more likely to contain the bacterium, especially in building hot water tanks and heaters and in water-cooled heat rejection devices such as air-conditioning cooling towers. The bacterium was found to be present in water 5–63°C (Fliermans, 1983) and to grow optimally in the environment between 25 and 40°C.

Rowbotham first proposed that *L. pneumophila* was a facultative parasite of free-living amoebae (Rowbotham, 1980a; Rowbotham, 1980b). His observations were confirmed by many other investigators (Tyndall and Domingue, 1982; Anand et al., 1983; Holden et al., 1984; Newsome et al., 1985; Henke and Seidel, 1986), and an association between outbreaks of Legionnaires' disease and the presence of amoebae was demonstrated by Fields and colleagues (Barbaree et al., 1986). The relative chlorine resistance of environmental *L. pneumophila* was explained in part by the protection afforded the bacterium growing within an amoebal cyst (Kilvington and Price, 1990), and the phenotype change of the bacterium resulting from intra-amoebal growth (Kilvington and Price, 1990; Barker et al., 1992; 1993). In addition, the growth-potentiating properties of some water specimens for *L. pneumophila* was explained by the multiplication of the bacterium in the amoebae (Yee and Wadowsky, 1982; Wadowsky et al., 1988; 1991). It is now accepted by most authorities that *L. pneumophila*, and probably most other *Legionella* spp., are facultative parasites of free-living amoebae, and that the major, if not sole form, of the organism in the environment is within amoebae. Not all *Legionella* bacteria will grow in the same amoebal host, indicating strain-to-strain variation in the selection of the optimal amoebal host (Rowbotham, 1986; Fields et al., 1989; 1990; Wadowsky et al., 1991). Of note, a number of other environmental bacteria pathogenic for man are now thought to grow within amoebae, including *Mycobacterium avium* and *Burkholderia pseudomallei* (Steinert et al., 1998; Cirillo et al., 1997; Michel and Hauröder, 1997; Marolda et al., 1999; Landers et al., 2000).

A number of biofilm studies have indicated that the bacterium grows within environmental biofilm, which contain a rich array of other bac-

teria and amoebae (Wright et al., 1989; Rogers and Keevil, 1992a; Green and Pirrie, 1993; Walker et al., 1993). The bacterium is present in highest concentration in the sessile population, but there is an equilibrium with the planktonic population (Rogers and Keevil, 1992a; Ta et al., 1995). One investigator has found that *L. pneumophila* grows in an experimental biofilm in the absence of amoebae, suggesting that the environmental growth of the organism can be quite complex (Rogers and Keevil, 1992a). Because many epidemics of Legionnaires' disease have been associated with sudden changes in water pressure within plumbing pipes, it is likely that the pressure fluxes cause release and distribution of the sessile biofilm containing large quantities of the bacterium. This is supported by one study showing a dramatic increase in *L. pneumophila* recovery after pressure shock of a plumbing system (Shands et al., 1985).

Growth of *L. pneumophila* within amoebae can enhance the virulence of the bacterium for macrophages and immunocompromised mice (Brieland et al., 1996; Cirillo et al., 1994). In addition, *L. pneumophila* grows to high concentrations within amoebae, and residence of the bacteria within the amoebae may protect the bacterium from the harmful effects of aerosolization. These facts have led to the unproven hypothesis that the infective form of the bacterium for man is via a "packet" of bacteria contained within an amoebal vacuole or cyst. A large body of literature exists regarding the molecular and cellular pathogenesis of *L. pneumophila* for amoebae, and its relationship to pathogenicity for macrophages; this topic is covered in the pathogenesis section of this review.

A viable but not cultivatable form of *L. pneumophila* has been proposed by a few investigators (Paszko-Kolva et al., 1992; Paszko-Kolva et al., 1993; Hay et al., 1995; Yamamoto et al., 1996; Steinert et al., 1997; Hussong et al., 1987). It is unclear if at least some of the reports of environmental viable but "not cultivatable" *L. pneumophila* isolates were "noncultivable" because they were in amoebae, and required prolonged incubation to amplify the small numbers present (Shahamat et al., 1991; Sanden et al., 1992). Another speculation (recently reported) is that this state represents a part of the developmental cycle of *L. pneumophila* (Garduno et al., 2000); if so the bacterium enters a vegetative cycle under different environmental conditions, which could make it easier to cultivate. Also, the significance of this phenomenon in the case of *Legionella* is uncertain. It is unknown if the viable but noncultivable bacteria, if they truly exist in nature, are pathogenic.

Environmental Microbiologic Techniques

Somewhat different selective media and techniques must be used for isolation from environmental specimens because of differences in contaminating bacterial and fungal flora. A commonly used and useful medium is BCYE α medium made selective with glycine, vancomycin, polymyxin B and natamycin; this is termed "MWY" or modified Wadowsky Yee medium (Wadowsky and Yee, 1981; Edelstein, 1982a). Another useful medium is BCYE α medium made selective with polymyxin E, cephalothin, vancomycin and cycloheximide, termed "CCVC" medium (Bopp et al., 1981). The latter is more inhibitory than MWY medium, and is best used for heavily contaminated specimens. Addition of differential dyes is used by some, but may not be especially useful (Vickers et al., 1981). Except for rare specimens, pretreatment of the specimen before plating with either acid (KCl, pH 4, for 4 min), or heat (60°C for 1–2 min) is required (Edelstein et al., 1982d).

Optimal yield of *L. pneumophila* from tap water specimens appears to be obtained by culturing of biofilm scraped from the interior of pipes and plumbing fixtures, as opposed to free flowing water from the same devices (Ta et al., 1995). Water specimens can be concentrated before plating by either centrifugation or filtration; both methods result in the loss of substantial and unpredictable amounts of bacteria (Boulanger and Edelstein, 1995). Centrifugation at low speed (3,800 \times g for 30 min) results in about 14% recovery, whereas higher speed centrifugation (8,000 \times g for 15 min) results in about 30% recovery. Filtration with flat membrane filters yields about 50% recovery, whereas filtration with woven membrane filters results in about 14% recovery.

Environmental Control and Remediation

Because *Legionella* bacteria are ubiquitous in the natural environment, as well as in many man-made environments, it is difficult (if not impossible) to eliminate the bacterium completely from many environmental sites. For the most part, this is unneeded, as the vast majority of Legionnaires' disease. The environmental sites that are most likely to transmit the disease include wet cooling towers, evaporative condensers, whirlpool spas, hot or tepid water potable water fixtures used for bathing or washing, and any medical equipment containing tap water that can be delivered into the lungs.

Attempts at quantifying the risk of Legionnaires' disease based on the concentration of *L. pneumophila* in water are unreliable scien-

tifically, and of unproven utility (http://www.osha-slc.gov/dts/osta/otm/otm_iii/otm_iii_7.html#1) (Shelton et al., 1993; 1994). This is because of the natural variability of bacterial growth in environmental sources, the heterogeneous nature of the bacterium in biofilm, and the low sensitivity and imprecision of concentration techniques. Other factors of unknown or imprecisely known risk include the presence of susceptible hosts, adequate aerosolization of the bacterium, viability of the bacterium in aerosols, and virulence of the bacteria. It is plausible that very high concentrations of *L. pneumophila* in water sources are a higher risk than very low concentrations, but exactly what constitutes a risk is not known. Despite this, various regulatory agencies have adopted the use of "action" limits for environmental *Legionella* bacteria www.osha-slc.gov (http://www.osha-slc.gov/dts/osta/otm/otm_iii/otm_iii_7.html#1); www.env.gov.sg (<http://www.env.gov.sg/cop/qed/remedial.html>).

Prevention of Legionnaires' disease should be based primarily on good engineering design and maintenance of plumbing systems, cooling towers, and spas. The factors important for minimizing the presence of *L. pneumophila* in plumbing systems include maintaining hot water temperatures >50°C, keeping cold water and cold water pipes <20°C, and eliminating blind loops and dead ends, thereby reducing stagnation (Brundrett, 1992; Freije, 1996; Anonymous, 1988; Chartered Institution of Building Services Engineers, 1987; Chartered Institution of Building Services Engineers, 1991; Department of Health and Social Security and the Welsh Office, 1989; Health and Safety Executive, 1991; Health and Safety Executive, 1998; Occupational Health S. A. W. C., 1995; Allegheny County Health Department, 1993; Wise et al., 1987; Brundrett, 1994). Also, elimination of hot water storage tanks, and use of water heaters with internal recirculation are important. Cooling towers require frequent cleaning, proper maintenance to control biofouling, drift eliminators, and siting of air intake ducts away from cooling tower drift (Butler et al., 1997; Anonymous, 1996; Broadbent, 1987; Brundrett, 1994). Spas require rigorous daily cleaning which includes emptying, scrubbing, and hyperchlorination, regular flushing of filters, and maintenance of an oxidizing residual at all times that is bioeffective; this requires limits on the numbers of users and hourly checks of free biocide concentration (National Center for Environmental Health and National Center for Infectious Diseases, 1995; Public Health Laboratory Service Spa Pools Working Party, 1994; Anonymous, 1985).

Whether to routinely monitor potable water and cooling tower water for the presence of *Legionella* is controversial (Yu, 1998; Breiman

and Butler, 1998; Butler et al., 1997; Tablan et al., 1994). This is because of the ubiquitous presence of the organism in most cooling tower water, and the relatively low frequency of Legionnaires' disease. Routine bacteriologic monitoring of the water distribution systems of health care facilities is least controversial, and is practiced by some health districts (Allegheny County Health Department, 1993; Anonymous, 2000).

Control of Legionella-contaminated sites can be divided into two main categories: measures to end an epidemic that implicates the particular environmental source, and measures to reduce bacterial concentration for other reasons [www.hse.gov.uk \(http://www.hse.gov.uk/pubns/misc150.pdf\)](http://www.hse.gov.uk/pubns/misc150.pdf); [www.tarn-pure.com \(http://www.tarn-pure.com\)](http://www.tarn-pure.com); [www.hcinfo.com \(http://www.hcinfo.com\)](http://www.hcinfo.com); [www.osha-slc.gov \(http://www.osha-slc.gov/dts/osta/otm/otm_iii/otm_iii_7.html\)](http://www.osha-slc.gov); (Brundrett, 1992; Health and Safety Commission, 1991; Health and Safety Executive, 1991; 1998; Freije, 1996). In the first category, shut down of implicated aerosol disseminators is the first step to be taken. Then application of oxidizing chemicals, usually chlorine, is instituted. In cooling towers, addition of an antifoaming agent is often needed. After the towers are disinfected, then thorough cleaning is needed. In the case of plumbing systems, extensive modifications are sometimes needed, which include elimination of dead legs, insulation of cold and hot water pipes to maintain temperatures $<20^{\circ}\text{C}$ and $>50^{\circ}\text{C}$, respectively, removal and cleaning or sterilization of distal fixtures, and removal of hot water storage tanks from the plumbing systems. Once an outbreak is controlled, then continuous maintenance of effective biocide concentrations is required. In some cases, the continuous biocide used has been chlorine or chlorine dioxide. Addition of a copper-silver ionization system has been effective in many settings, but usually only when needed plumbing modifications have been made, and when an oxidizing compound is used as well (Biurrun et al., 1999; Rohr et al., 1999; Lin et al., 1998; Miuetzner et al., 1997). Hard water compromises the efficacy of the copper-silver ionization system.

Pathogenesis

Given that legionellosis is most associated with infection by *L. pneumophila* (see above), the vast majority of studies on pathogenesis have focused on that species of *Legionella* and, in particular, strains belonging to its first serogroup. Therefore, the following description of pathogenesis should formally be viewed as an account of *L. pneumophila* (serogroup 1) pathogenesis.

The notable observations that have been made with the other *Legionella* species will be highlighted at the end of this section.

An Overview

Legionella pneumophila infects humans following either the inhalation of contaminated aerosols generated by airconditioners, showers and other devices or the aspiration of contaminated potable water (Mahoney et al., 1992; Woo et al., 1992). Once delivered into the respiratory tract, the organism invades and proliferates within the resident macrophages that line the alveoli (Cianciotto et al., 1989a; Horwitz, 1992; Winn, 1988). The release of tissue-destructive substances from the bacteria undoubtedly contributes to pathology (Cianciotto et al., 1989a; Winn, 1988). As a result of this intracellular multiplication, polymorphonuclear leukocytes (PMNs), additional macrophages (i.e., differentiated monocytes), and erythrocytes infiltrate the alveoli, and capillary leakage results in local edema (Winn, 1988). This and further host defense responses are triggered, at least in part, by chemokines and proinflammatory cytokines (i.e., IL-1, IL-6, GM-CSF, MCP-3, MIP-1 α , MIP-2 and TNF- α) released by the infected macrophages (Blanchard et al., 1987; Nakachi et al., 2000; Widen et al., 1991; Yamamoto et al., 1995). Although it is quite clear that the legionellae do not replicate within the recruited PMNs, data are still conflicting as to the ability of these phagocytes to effectively kill ingested bacteria (Blanchard et al., 1989; Fitzgeorge et al., 1988; Horwitz and Silverstein, 1981; Katz and Hashemi, 1982). In contrast, when the cell-mediated adaptive immune response is functioning normally, further bacterial amplification is usually limited (Breiman and Horwitz, 1987; Friedman et al., 1998; Horwitz, 1992; Klein et al., 1991; Skerrett and Martin, 1992). Most evidence points to a critical role for the Th1 T-cell response and its associated cytokines (e.g., γ -interferon [γ -IFN] and interleukin-12) in the clearance of *L. pneumophila* (Brieland et al., 1998; Heath et al., 1996; Kitsukawa et al., 1995; Newton et al., 2000; Skerrett and Martin, 1994; Susa et al., 1998; Tateda et al., 1998). Indeed, γ -IFN activation of macrophages renders the cells nonpermissive for the *Legionella* parasite (Bhardwaj et al., 1986; Fujio et al., 1992; Jensen et al., 1987; Klein et al., 1991; Nash et al., 1988; Skerrett and Martin, 1992; Watanabe et al., 1993). When adaptive immune response is impaired in certain immunocompromised individuals, bacterial proliferation and extrapulmonary dissemination are pronounced, and disease may be fatal (Doebbeling and Wenzel, 1987; Skerrett and Martin, 1992; Winn, 1988).

Animal models have been an invaluable tool for determining the basic course of an *L. pneumophila* infection, the role of particular bacterial factors in pathogenesis, and the basis of host defense (Cianciotto et al., 1989a; Collins, 1986). Legionellosis is most often reproduced by infection of guinea pigs, corticosteroid-treated rats, or A/J mice, using the aerosol or intratracheal routes of inoculation (Baskerville et al., 1983; Berendt et al., 1980; Brieland et al., 1994; Davis et al., 1982; 1983; Edelstein et al., 1984; Skerrett et al., 1989; Susa et al., 1998; Twisk-Meijssen et al., 1987; Winn et al., 1982). Interestingly, a number of inbred mice are not susceptible to *L. pneumophila*, and thus crosses between them and the A/J animals are being used to identify mammalian loci (e.g., *Lgn1*) that influence host susceptibility (Beckers et al., 1995; Dietrich et al., 1995; Diez et al., 1997; Gowney et al., 2000; Yamamoto et al., 1992; Yoshida et al., 1991).

The Relative Importance of Intracellular Infection and Extracellular Survival

Much evidence indicates that the capacity of the *L. pneumophila* to grow within alveolar macrophages is central to the pathogenesis of Legionnaires' disease. First, the majority of bacteria observed in lung samples from infected humans and animals are associated with these cells (Chandler et al., 1979a; Davis et al., 1983; Glavin et al., 1979; Katz et al., 1979; Rodgers et al., 1978; Surgot et al., 1988; Watson and Sun, 1981; White et al., 1979). Second, *L. pneumophila* readily replicates within alveolar macrophages and monocytes in vitro (Horwitz and Silverstein, 1980; Jacobs et al., 1984; Kishimoto et al., 1979; Nash et al., 1984). Third, the susceptibility of an animal species to infection is correlated with the ability of *L. pneumophila* to grow within macrophages from that species (Yamamoto et al., 1987; Yamamoto et al., 1988; Yoshida and Mizuguchi, 1986). Fourth, the resistance of animals to infection requires γ -IFN, the cytokine that activates macrophages (Brieland et al., 1994; Skerrett and Martin, 1994). Fifth, mutants that are impaired in their ability to infect macrophages exhibit reduced virulence (Cianciotto et al., 1990b; Edelstein et al., 1999c; Jacobs et al., 1984; Liles et al., 1999; Marra et al., 1992; Pearlman et al., 1988; Viswanathan et al., 2000). Finally, as noted earlier, therapy requires antibiotics that enter eukaryotic cells (Winn, 1988).

Despite the early recognition of the Legionella-macrophage interaction, it was not immediately obvious how *L. pneumophila*, an organism that neither possesses a mammalian reservoir nor exhibits a "natural" route of infection, evolved the facility to parasitize human

phagocytes. It is now believed that adaptation to intracellular niches within protozoa engendered in *L. pneumophila* the ability to infect mammalian cells (Atlas, 1999; Cianciotto and Fields, 1992; Fields, 1996; Harb et al., 2000b; Swanson and Hammer, 2000). Several observations signal that the requirements for growth within macrophages mimic those in protozoa. First, the intracellular pathway pursued by the *Legionella* parasite, which includes replication within a membrane-bound vesicle (phagosome), is remarkably similar in protozoa and macrophages (Abu Kwaik, 1996a; Bozue and Johnson, 1996; Horwitz, 1983a; Newsome et al., 1985; Rowbotham, 1986). Second, bacteria grown in amoebae maintain their ability to infect macrophages and to cause disease (Steinert et al., 1994; Vandenesch et al., 1990). Indeed, amoeba-grown *L. pneumophila* are more infective for macrophages and epithelial cells than are agar-grown organisms (Cirillo et al., 1994). Third, strains that have been rendered avirulent by passage on artificial media are unable to infect both protozoa and macrophages (Fields et al., 1986; Rowbotham, 1986). Finally, as a form of genetic proof, a variety of mutants are similarly impaired in their ability to infect macrophages and protozoans (Cianciotto and Fields, 1992; Gao et al., 1997; Liles et al., 1999; Segal and Shuman, 1999a). Hence, a number of virulence factors likely evolved in response to selective pressures within the protozoan environment.

Without diminishing the significance of growth within macrophages, it is likely that other factors also contribute to the survival of *L. pneumophila* within humans. For example, the bacterium may replicate or, at a minimum, must survive within extracellular spaces in the alveoli (Chandler et al., 1979a; Rodgers et al., 1978; Surgot et al., 1988; Watson and Sun, 1981; White et al., 1979). The fact that many strains of *L. pneumophila* are inherently serum resistant may be particularly relevant for extracellular survival following the onset of the inflammatory response (Caparon and Johnson, 1988; Horwitz and Silverstein, 1981; Luneberg et al., 1998; Plouffe et al., 1985; Verbrugh et al., 1985). Similarly, the ability of the bacterium to resist cationic peptides and to secrete enzymes that degrade surfactant suggests that it might subvert antimicrobial factors released by lung epithelia (M. Robey, W. O'Connell and N. P. Cianciotto, 2001; Edelstein, 1981; Flieger et al., 2000b; Wadowsky and Yee, 1981). The presence of legionellae within non-macrophage cells in necropsy material suggests that *L. pneumophila* also may grow within the alveolar epithelium (Rodgers, 1979; Watson and Sun, 1981). In support of this notion, the microbe can replicate within alveolar types I and II cells, as well as a variety of other epithelial cells in

vitro (Cianciotto et al., 1995; Mody et al., 1993). The importance of extra-macrophage niches or processes is also implied by two additional observations. First, those *L. pneumophila* clone types that most often represent the clinical isolates (which are MAb-2 positive) are not necessarily more effective at intracellular infection (Edelstein and Edelstein, 1993b). Second, some genetically defined mutants that are not defective or only moderately defective for macrophage infection in vitro are strikingly impaired in animal models of virulence (Edelstein et al., 1999c; Liles et al., 1999).

The Intracellular Infection Process

Given the pivotal role that intracellular parasitism plays in the biology of *L. pneumophila*, a first-line approach toward understanding legionellosis has been to study the cellular basis of macrophage infection (Abu Kwaik, 1998a; Cianciotto et al., 1989a; Horwitz, 1992; Ott, 1994; Roy, 1999; Shuman et al., 1998; Swanson and Hammer, 2000; Vogel and Isberg, 1999). This effort has been aided enormously by the availability of human macrophage-like cell lines, such as U937, HL-60, Mono Mac, and THP-1 cells (Cirillo et al., 1994; Marra et al., 1990; Neumeister et al., 1997; Pearlman et al., 1988).

Initially, strains of *L. pneumophila* enter the macrophage by conventional or coiling phagocytosis, processes that are dependent on the host cell actin cytoskeleton (Elliott and Winn, 1986; Horwitz, 1984a; King et al., 1991; Rechnitzer and Blom, 1989). Some studies indicate that phagocytosis involves opsonization of the bacteria with the complement component C3 and the subsequent binding to complement receptors CR1 and CR3 (Payne and Horwitz, 1987). Entry via this pathway appears to limit the phagocyte's oxidative burst and thereby may help to facilitate subsequent bacterial intracellular survival (Jacob et al., 1994). Other reports, however, have stressed the importance of opsonin-independent phagocytosis (Gibson et al., 1994; Husmann and Johnson, 1992; Rodgers and Gibson, 1993; Steinert et al., 1994). When the legionellae are grown in amoebae, as opposed to bacteriologic media, their entrance into monocytes is more likely to involve complement-independent, coiling phagocytic events (Cirillo et al., 1999). Although this alternate mode of entry may elicit an oxidative burst, it should be noted that a number of *L. pneumophila* strains exhibit innate resistance to hydrogen peroxide, superoxide anion, and hydroxyl radicals (Jepras and Fitzgeorge, 1986; Lochner et al., 1983). After entry into the macrophage host is complete, the legionellae reside within a phagosome that is unusual for its hypoexpression of major histocompatibility

(MHC) antigens (Clemens and Horwitz, 1992; Clemens and Horwitz, 1993). This nascent phagosome does not fuse with early or late endosomes or lysosomes (Clemens and Horwitz, 1995; Clemens et al., 2000; Horwitz, 1983b). As a result of this form of phagosome trafficking, *L. pneumophila* escapes the killing that is promoted by vacuolar acidification and lysosomal degradation and reduces or delays the association of its protein with MHC Class II that is required for antigen presentation (Clemens and Horwitz, 1995; Horwitz, 1983b; Horwitz and Maxfield, 1984b; Wiater et al., 1998). Within 4–12 h post-infection, mitochondria, smooth vesicles and rough endoplasmic reticulum surround the *L. pneumophila* phagosome, a process that is orchestrated by the bacterial parasite (Coers et al., 1999; Glavin et al., 1979; Horwitz, 1983a; Swanson and Isberg, 1995). A recent study suggests that, late in the intracellular cycle (i.e., 12–24 h), the *Legionella* phagosome does fuse with acidic lysosomal compartments, but bacterial growth continues (Sturgill-Koszycki and Swanson, 2000). Within its specialized niches, the legionellae replicate by binary fission, creating a large phagosome that fills much of the host cell (Abu Kwaik, 1996a; Horwitz, 1983a). Intracellular replication itself is significantly influenced by host cell iron and thymidine levels (Byrd and Horwitz, 1989; Byrd and Horwitz, 1991; Byrd and Horwitz, 2000; Gebran et al., 1994; Hickey and Cianciotto, 1997; Mengaud and Horwitz, 1993; Mintz et al., 1988; Pope et al., 1996; Stone et al., 1999b). Ultimately, *L. pneumophila* intracellular infection results in the death and lysis of the host cell. Macrophage death appears to involve an early induction of caspase-3 mediated apoptosis and a late form of necrosis triggered by a bacterial pore-forming activity (Alli et al., 2000; Gao and Abu Kwaik, 1999a; Gao and Abu Kwaik, 1999b; Hagele et al., 1998; Muller et al., 1996). In contrast to the series of events just outlined, exposure of a macrophage to large numbers of attached (extracellular) *L. pneumophila* results in immediate pore formation in the host cell plasma membrane and rapid necrotic cell death (Husmann and Johnson, 1994; Kirby et al., 1998; Zuckman et al., 1999).

Virulence Factors of *L. pneumophila*

Microbiological, biochemical, ultrastructural and genetic approaches have identified some of the factors that may potentiate *L. pneumophila* intracellular infection and/or virulence (Abu Kwaik, 1998a; Belyi, 1999; Cianciotto et al., 1989a; Dowling et al., 1992; Hacker et al., 1993; Swanson and Hammer, 2000). Among the genetic tools for manipulating *L. pneumophila* are the methods of conjugal transfer from

recombinant *Escherichia coli*, electroporation of recombinant plasmids, allelic exchange (directed) mutagenesis, random mutagenesis with mini-Tn10 transposons, shuttle and signature-tagged mutagenesis, reporter gene fusions, and differential display (Abu Kwaik and Pederson, 1996b; Albano et al., 1992; Chen et al., 1984; Cianciotto and Fields, 1992; Cianciotto et al., 1988; Dreyfus and Iglewski, 1985; Edelstein et al., 1999c; Engleberg et al., 1988; Hickey and Cianciotto, 1997; Kohler et al., 2000; Marra and Shuman, 1989; McClain and Engleberg, 1996a; Mintz and Shuman, 1987; Pope et al., 1994; Tully et al., 1992; Wiater et al., 1994a; 1994b).

One of the earliest observations concerning *L. pneumophila* virulence was the finding that legionellae passaged on bacteriologic media had the potential to be converted to an avirulent state (Elliott and Johnson, 1982; McDade and Shepard, 1979). This virulent to avirulent conversion is heavily influenced by the nature of the medium; e. g., high-salt supplemented-Mueller-Hinton agar favors the growth of avirulent forms, whereas growth of the virulent strain can be maintained on buffered charcoal yeast extract (BCYE) agar so long as a reasonable passage number is not exceeded (Catrenich and Johnson, 1988; Catrenich and Johnson, 1989; Horwitz, 1987; Nowicki et al., 1987; Yamamoto et al., 1993). The second factor to potentiate the ability of *L. pneumophila* to infect human cells is its growth phase; i. e., stationary phase bacteria are more infective than are exponential phase organisms (Byrne and Swanson, 1998). This conversion in phenotype is triggered by amino acid depletion and involves an intracellular accumulation of ppGpp, the classic indicator of the bacterial stringent response (Hammer and Swanson, 1999). Iron limitation also reversibly diminishes the virulence of *L. pneumophila*, signaling the importance of iron uptake in *Legionella* pathogenesis (see below; James et al., 1995). Finally, growth temperature has been found to have a variable and relatively minor influence on *L. pneumophila* virulence and intracellular infectivity (Berg et al., 1985; Edelstein et al., 1987b; Mauchline et al., 1994).

As is often the case for bacterial pathogens, a variety of *L. pneumophila* surface structures and molecules have been implicated in pathogenesis. The *L. pneumophila* LPS, in addition to bearing the serogroup-specific O antigen (see above), contains endotoxin (Ciesielski et al., 1986; Conlan and Ashworth, 1986a; Highsmith et al., 1978; Nolte et al., 1986; Otten et al., 1986). However, the LPS-lipid A of *Legionella* possesses a relatively weak endotoxic activity that appears to be due to its low affinity for the CD14 receptor on macrophages (Neumeister et al., 1998a; Schramek et al., 1982; Wong et al., 1979). Inter-

estingly, a particular LPS epitope, which is recognized by the typing MAb 2, is more frequently expressed on clinical versus environmental isolates of serogroup 1 strains (Dournon et al., 1988; Helbig et al., 1995; Zou et al., 1999). However, mutational analysis has determined that loss of that epitope itself does not diminish the ability of *L. pneumophila* to infect macrophages or protozoa (Mintz and Zou, 1992b). On the other hand, several recent studies have correlated other antigenic changes in LPS expression with reductions in serum resistance, intracellular growth, and virulence (Luneberg et al., 1998; Rogers et al., 1992b). Finally, mutation of a gene (*rcp*) that appears to modify lipid A structure reduces the ability of *L. pneumophila* to resist cationic antimicrobial peptides (i. e., polymyxin and defensin C18G) and to infect host cells (M. Robey, W. O'Connell, and N. P. Cianciotto, manuscript submitted). A second prominent surface feature of *L. pneumophila* is its flagella (Chandler et al., 1980; Rodgers et al., 1980a). The gene encoding the flagellin subunit has been cloned, sequenced, and found to be regulated by temperature, growth phase, amino acids, viscosity and osmolarity (Hammer and Swanson, 1999; Heuner et al., 1995; Heuner et al., 1999; Ott et al., 1991). Although mutational analyses indicate that *Legionella* flagella are not required for intracellular replication per se, they appear to promote bacterial entry into host cells (Merriam et al., 1997; Pruckler et al., 1995a; Dietrich et al., 2000; Ross et al., 2000). *Legionella pneumophila* have at least two types of pili (Chandler et al., 1980; Rodgers et al., 1980a; Stone and Abu Kwaik, 1998). One form includes the temperature-regulated, bundle-forming type IV pili, which facilitate to a modest degree bacterial attachment to host cells (Liles et al., 1998; Stone and Abu Kwaik, 1998). A fourth *L. pneumophila* surface structure is the genus-wide, peptidoglycan-linked, outer membrane porin (Gabay et al., 1985; Hoffman et al., 1992a; Hoffman et al., 1992b). Notably, this 28-kDa protein, which is also known as the major outer membrane protein (MOMP) of *L. pneumophila*, is a binding site for complement components and thus mediates opsonophagocytosis (Bellinger-Kawahara and Horwitz, 1990). The 24-kDa Mip is another genus-wide, surface-exposed membrane protein, which exists as a homodimer and possesses prolyl-proline isomerase (PPIase) activity (Cianciotto et al., 1990a; Engleberg et al., 1989; Fischer et al., 1992; Riffard et al., 1996; Schmidt et al., 1994). The *mip* gene is required for the early stages of intracellular infection of macrophages, protozoa, and lung epithelia and for virulence following intratracheal inoculation of guinea pigs (Cianciotto et al., 1989b; 1990b; 1995; Cianciotto and Fields, 1992; Susa et al., 1996; Winter-

meyer et al., 1995). The analysis of Mip, in addition to providing for the first definition of a *Legionella* virulence factor, has now yielded the first crystal structure of a *Legionella* protein (Cianciotto et al., 1990b; Hilgenfeld et al., 2000). The final surface proteins that have received some attention are a 19-kDa outer membrane lipoprotein, a 25-kDa MOMP and a 60-kDa heat shock protein (Hsp60; Garduno et al., 1998a; High et al., 1993; Hindahl and Iglewski, 1987; Hoffman et al., 1990; Sampson et al., 1990). Although the genus-wide, lipoprotein gene has been cloned and sequenced (Engleberg et al., 1991; Ludwig et al., 1991), examination of its role in pathogenesis has not been forthcoming. On the other hand, data suggest that the 25-kDa protein promotes bacterial attachment to a macrophage-like cell line (Krinis et al., 1999). The Hsp60 is induced upon intracellular infection and appears to promote epithelial cell invasion (Abu Kwaik et al., 1993; Fernandez et al., 1996; Garduno et al., 1998b). Furthermore, it elicits proinflammatory cytokine (e.g., IL-1) expression by macrophages (Retzlaff et al., 1994; 1996).

Much work has highlighted the importance of *Legionella* protein secretion systems for pathogenesis. For some time, it has been known that *L. pneumophila* secretes a variety of degradative enzymes, when it is grown in or on bacteriologic media (Baine et al., 1979b; Baine, 1985; Müller, 1981; Nolte et al., 1982; Thorpe and Miller, 1981). Recent studies indicate that many of these factors, including two acid phosphatases, an RNase, a zinc metalloprotease, a monoacylglycerol lipase, a phospholipase A, a lysophospholipase A, and a *p*-nitrophenylphosphorylcholine hydrolase (previously, viewed as a phospholipase C), are secreted via a type II protein secretion system, which is itself dependent upon the type IV prepilin peptidase (PilD; O. Rossier and N. P. Cianciotto, 2001; Aragon et al., 2000; Aragon et al., 2001; Flieger et al., 2000a; Hales and Shuman, 1999a; Liles et al., 1998; Liles et al., 1999). Mutations within the genes encoding the secretion system reduce the ability of *L. pneumophila* to infect both human macrophages and protozoa, suggesting that one or more of the type II exoproteins are virulence determinants (O. Rossier and N. P. Cianciotto, manuscript submitted; Hales and Shuman, 1999a). The behavior of mutants specifically defective in single exoproteins has thus far eliminated essential intracellular infection roles for the metalloprotease, the major acid phosphatase, and the *p*-nitrophenylphosphorylcholine hydrolase (Aragon et al., 2000; Aragon et al., 2001; Moffat et al., 1994; Szeto and Shuman, 1990). The metalloprotease is at best a weak virulence factor in vivo, inhibiting the chemotactic response and oxidative burst of neutrophils, promoting some

pulmonary damage and cell cytotoxicity, and degrading a variety of substrates such as IL-2 (Baskerville et al., 1986; Blander et al., 1990; Conlan et al., 1988a; Dreyfus and Iglewski, 1986; Edelstein et al., 1999c; Mintz et al., 1993; Moffat et al., 1994; Müller, 1980; Quinn and Tompkins, 1989; Rechnitzer and Kharazmi, 1992; Sahney et al., 1990; Williams et al., 1987). *Legionella pneumophila* does possess a variety of proteases, and presumably some of them can, if necessary, function in the absence of the zinc metalloprotease (Berdal and Olsvik, 1983; Conlan et al., 1986b; Conlan et al., 1988b; Gul'nik et al., 1986). Interestingly, a mutation in the PilD peptidase gene leads to both a sharp reduction in animal virulence and a more dramatic reduction in intracellular infection than do mutations of genes for either the type II secretion system or the type IV pilus (O. Rossier and N. P. Cianciotto, manuscript submitted; Liles et al., 1999). These data suggest the existence of another, potentially novel secretion pathway that promotes bacterial pathogenesis. A second type of protein secretion system that clearly exists within *L. pneumophila* and promotes intracellular infection is a type IV system (Christie and Vogel, 2000). This system, which is dependent upon a large number of genes contained within the so-called "defective for organelle trafficking" (*dot*) and "intracellular multiplication" (*icm*) loci, is critical for the ability of *L. pneumophila* to inhibit phagosome-endolysosomal fusions and to establish its unique replicative niche (Andrews et al., 1998; Berger and Isberg, 1993; Berger et al., 1994; Brand et al., 1994; Marra et al., 1992; Purcell and Shuman, 1998; Sadosky et al., 1993; Segal et al., 1998b; Segal and Shuman, 1997; Vogel et al., 1998). Several *icm/icm* loci also have been shown to be essential for virulence in a guinea pig model of disease (Edelstein et al., 1999c; Marra et al., 1992). Interestingly, the Dot/Icm secretion system is also structurally and functionally homologous to bacterial conjugation systems (Segal and Shuman, 1998a; Segal et al., 1998b; Vogel et al., 1998). Among the factors believed to constitute the secretion apparatus, DotA is clearly an inner membrane protein that plays a critical role in the initial trafficking of the *Legionella* phagosome (Roy et al., 1998; Roy and Isberg, 1997; Swanson and Isberg, 1996; Wiater et al., 1998). Aside from the IcmX protein, the factors secreted by the *Legionella* Dot/Icm system remain largely unknown (Matthews and Roy, 2000; Zuckman et al., 1999). Recently, a second *L. pneumophila* type IV secretion system (i.e., the *lvh* system) was identified, although it proved not to be critical for intracellular infection (Segal et al., 1999b). One of the earliest described, putative virulence factors of *L. pneumophila* is a heat-stable peptide toxin that appears in culture

supernatants (Friedman et al., 1980; Hedlund, 1981). Although partially purified peptide toxin was found to inhibit the oxidative burst of PMNs (Friedman et al., 1982; Lochner et al., 1985), the inability to purify the toxin and/or define its genetic basis have prevented an assessment of its overall importance for pathogenesis (Dowling et al., 1992). The most obvious secreted product of *L. pneumophila* is actually not a protein but rather a brown pigment, a polymer of homogentisic acid whose production requires a tyrosine-containing medium and the genus-wide legiolsin (*lly*) gene (Baine and Rasheed, 1979a; Bender et al., 1991; Wintermeyer et al., 1991). Mutants in *lly*, however, are not impaired in intracellular infection, although they are, interestingly, hypersensitive to light (Steinert et al., 1995; Wiater et al., 1994b; Wintermeyer et al., 1994).

Several putative virulence factors, especially stress-response enzymes, have been localized to the *L. pneumophila* periplasm or cytoplasm or both (Pine et al., 1984). A copper-zinc superoxide dismutase (SOD) resides in the *Legionella* periplasm, affording resistance to toxic superoxide anions (by converting them to H₂O₂, see below) and promoting survival during stationary phase (St. John and Steinman, 1996). Mutational analysis indicates, however, that the enzyme is not required for bacterial infection of macrophages. A second SOD, which bears iron as its cofactor and exists within the *Legionella* cytoplasm, is essential for bacterial viability, and thus its role in pathogenesis cannot be assessed by the genetic approach (Sadosky et al., 1994; Steinman, 1992).

Legionella pneumophila possesses two catalase-peroxidases, enzymes that convert H₂O₂ to innocuous water and oxygen (Bandyopadhyay and Steinman, 1998). The KatA catalase-peroxidase, like the CuZn-SOD, is located in the periplasm and is induced during stationary phase (Amemura-Maekawa et al., 1999). The KatB enzyme is cytoplasmic, and, importantly, recent mutational analysis has identified a role for the *katB* gene in intracellular infection (Bandyopadhyay and Steinman, 1998). A third type of enzyme that is associated with the *L. pneumophila* periplasm is an alkaline phosphatase (Kim et al., 1994). However, mutants that are defective in the production of the enzyme are not impaired in intracellular infection of macrophages. The *Legionella* *hel* locus, which is predicted to encode an inner membrane heavy metal transporter, also is not required for intracellular growth, but does appear to promote host cytotoxicity (Arroyo et al., 1994; McClain et al., 1996b). In addition to the surface-associated Mip (see above), an *L. pneumophila* PPIase, known as Cyp18, has been identified in the bacterial cyto-

plasm (Schmidt et al., 1996). Because the mutant strain defective for Cyp18 has been only tested in amoebal infection, the importance of this second PPIase for pathogenesis remains unclear. The *L. pneumophila* global stress protein GspA, stationary-phase σ factor RpoS, pyrophosphatase Ppa, and the novel LigA protein are induced by stress and macrophage infection (Abu Kwaik, 1998b; Abu Kwaik and Engleberg, 1994; Hales and Shuman, 1999b; Susa et al., 1996). Mutational analysis has determined that at least GspA, RpoS and LigA are not required for macrophage infection (Abu Kwaik et al., 1997; Fettes et al., 2000). Finally, the *L. pneumophila* *oad* (oxaloacetate decarboxylase), *asd* (aspartate- β -semialdehyde), *pts* (phosphoenolpyruvate phosphotransferase) and *prp* (propionate catabolism) genes enhance intracellular infection (Edelstein et al., 1999c; Harb and Abu Kwaik, 1998; Jain et al., 1996; Stone et al., 1999b; Higa and Edelstein, 2000).

Recent screens of randomly mutagenized legionellae as well as differential display-PCR have uncovered a large number of other genes that promote intracellular infection (Abu Kwaik and Pederson, 1996b; Cirillo et al., 2000; Gao et al., 1997; Gao et al., 1998; Pope et al., 1996; Swanson and Isberg, 1996). Collectively, these loci promote all the various stages of intracellular infection; i.e., entry, intracellular survival and trafficking, replication, and escape. Whereas some of these genes (e.g., the phosphomannose isomerase [*pmi*] gene) promote protozoan and macrophage infection to similar degrees, others (e.g., macrophage-specific infectivity locus [*mil*]) are particularly important for the macrophage infection (Gao et al., 1997; Gao et al., 1998). For the most part, the structure, location and function of the corresponding gene products are unknown. However, the early macrophage locus (*eml*), enhanced entry (*enh*), and *milA* genes appear to encode novel proteins that are important during the early stages of infection, including entry and the formation of the replicative phagosome (Abu Kwaik and Pederson, 1996b; Cirillo et al., 2000; Harb and Abu Kwaik, 2000a). Other genes that are now known as the *rib* loci may encode a pore-forming toxin, which is associated with bacterial escape from the dying macrophage (Alli et al., 2000).

As can be appreciated from the above discussion of virulence factors, most research efforts have targeted those determinants involved in bacterial attachment, evasion of host defense, and tissue damage. Thus, aspects of bacterial nutrient acquisition and replication (per se) in vivo and in host cells remain largely unknown, as is often the case in analyses of other pathogens. However, one form of nutrient acquisition that has been addressed and is necessary for

pathogenesis is iron assimilation (V. K. Viswanathan and N. P. Cianciotto, 2001; Muller et al., 1983; Viswanathan et al., 2000; Owens et al., 1982). As expected, *L. pneumophila* iron acquisition is both important for intra- and extracellular replication and involves secreted and cell-associated factors. First, the organism excretes a siderophore, a high-affinity, nonproteinaceous ferric iron chelator that is unique in structure and has been designated as "legiobactin" (Liles et al., 2000). Because the genes encoding legiobactin are presently unknown, the role of the siderophore in intracellular infection and virulence has been difficult to gauge. On the other hand, genetic evidence does indicate that *L. pneumophila* produces a second siderophore, which is a hydroxymate-like molecule that may promote infection of macrophages (Hickey and Cianciotto, 1997). Analysis of another class of mutants indicates that *L. pneumophila* ferric iron acquisition and intracellular infection are also facilitated by genes encoding a unique methyltransferase (*iraA*), a membrane (iron-)peptide transporter (*iraB*), and the inner-membrane cytochrome *c* biogenesis system (*ccm*; V. K. Viswanathan et al., manuscript submitted; Pope et al., 1996; Viswanathan et al., 2000). Periplasmic and cytoplasmic ferric reductases aid in further iron assimilation, although their role in pathogenic processes has not been investigated (James et al., 1997; Johnson et al., 1991; Poch and Johnson, 1993). Given that bacterial pathogens usually access multiple iron sources, it is notable that *L. pneumophila* also can utilize heme-containing compounds (O'Connell et al., 1996). However, mutation of a *L. pneumophila* gene (*hbp*) that promotes hemin binding does not diminish intracellular infection (O'Connell et al., 1996). Some of the *L. pneumophila* iron acquisition genes appear to be controlled by ferric uptake regulator (Fur), a transcriptional regulator that senses intracellular iron levels (Hickey and Cianciotto, 1994; 1997; O'Connell et al., 1996). *Legionella* strains do not directly utilize lactoferrin or transferrin, two host iron chelators that are used by a number of other pathogens. In the case of lactoferrin, the legionellae can bind the host factor, but the interaction is bactericidal (Bortner et al., 1986; 1989). In the case of transferrin, the bacteria are simply incapable of binding the iron chelator (Goldoni et al., 1991; James et al., 1997; Johnson et al., 1991). It should be noted, however, that transferrin may be an indirect iron source for *L. pneumophila*; i.e., *Legionella* protease(s) can degrade transferrin, resulting in the release of ferric iron (James et al., 1997).

It is perhaps not surprising that the virulence determinants thus far identified or hypothesized are all involved, at least partially, in intracellular

infection. However, a recent study, which employed signature-tagged mutagenesis, has uncovered genes that appear relevant for non-macrophage related virulence (Edelstein et al., 1999c). Further analysis of these so-called *nmv* genes should prove quite interesting (Edelstein et al., 2000).

Pathogenic Aspects of *Legionella* Species Other Than *L. pneumophila*

Approximately one half of the *Legionella* species have been associated with human disease (see above). Many of these species, as well as some of the species that as yet have not been linked to cases of legionellosis, have the ability to infect and grow within macrophages (Fields et al., 1990; Arata et al., 1992; Izu et al., 1999; Levi et al., 1987; Maruta et al., 1998; Miyamoto et al., 1996; Neumeister et al., 1997; Weinbaum et al., 1984). Among the non-pneumophila species, *L. micdadei* has been examined the most for cellular and molecular aspects of intracellular infection (Dowling et al., 1992; Saha et al., 1988; Saha et al., 1989). Although strains of *L. micdadei* possess a functional Mip protein and induce apoptosis in and cytokine release by host cells (Gao et al., 1999c; Neumeister et al., 1998b; O'Connell et al., 1995), their mode of macrophage infection is notably different from that of *L. pneumophila*. For example, they, for the most part, do not reside within phagosomes that evade lysosomes and recruit rough endoplasmic reticulum (Gao et al., 1999c; Joshi and Swanson, 1999; Rechnitzer and Blom, 1989; Weinbaum et al., 1984). Interestingly, *L. dumoffii* partly multiplies free within the cytoplasm of non-macrophage hosts (Maruta et al., 1998). Thus, as the various legionellae become more associated with human disease, it will become increasingly important for researchers to examine them carefully and not assume that they are simple equivalents of *L. pneumophila*. Indeed, the emergence of *L. longbeachae* as a serious health threat in Australia has prompted initial inquiries into that species' infectivity determinants (Doyle et al., 1998).

The Genus *Haemophilus*

DORAN L. FINK AND JOSEPH W. ST. GEME III

Introduction

All members of the genus *Haemophilus* are small, pleomorphic, Gram-negative coccobacilli. The genus consists of diverse species, including some that are pathogens in humans and others that are pathogens in animals. Additional species are commensal organisms and are not associated with disease. The type species is *H. influenzae*, which was first isolated during the 1889 influenza pandemic and was originally believed to be the causative agent of influenza.

Taxonomy

Over the years, the taxonomy of the genus *Haemophilus* has been subject to considerable revision. At one time *Haemophilus* was included in the family Brucellaceae. In the eighth edition of {*Bergey's Manual of Determinative Bacteriology*} (Zinnemann and Biberstein, 1974), this genus was grouped with "Genera of Uncertain Affiliation." Since 1984, *Haemophilus* has been included along with *Actinobacillus* and *Pasteurella* in the family Pasteurellaceae (Kilian and Biberstein, 1984).

Traditionally *Haemophilus* species were defined based on the requirement for factor X or factor V or both for aerobic growth. However, in the present classification scheme, some species can grow without either of these factors. Furthermore, dependence on factor X or factor V is not definitive for *Haemophilus*, as some species of *Actinobacillus* and *Pasteurella* also require factor V.

As summarized in Table 1, *H. influenzae* (including biogroup aegyptius) and *H. haemolyticus* require both factor X and factor V, *H. parainfluenzae*, *H. parahaemolyticus*, *H. paraphrohaemolyticus*, *H. paraphrophilus*, *H. segnis*, *H. parasuis* and *H. paracuniculus* require factor V only, and *H. ducreyi* and *H. haemoglobinophilus* require factor X only. *Haemophilus paragallinarum* usually requires factor V, but factor V-independent *H. paragallinarum* strains also have been described and account for the

vast majority of isolates in certain geographic regions (Miflin et al., 1995). Similarly, *H. aphrophilus* sometimes requires factor X for primary isolation, but thereafter usually grows independently of both factor X and factor V. *Haemophilus somnus* and *H. agni* are closely related organisms that resemble the species *Histophilus ovis* and do not require either factor X or factor V; these organisms have not been validated as *Haemophilus* species and are referred to as species incertae sedis (of uncertain or doubtful affiliation). Some authors have suggested that *H. somnus* and *H. agni* be transferred to the genus *Histophilus*. Organisms that were formerly included in the genus *Haemophilus* include *Actinobacillus pleuropneumoniae* and *Taylorella equigenitalis*.

Beside the requirement for factor X or factor V or both, other criteria that facilitate distinction of one *Haemophilus* species from another include the ability to lyse horse erythrocytes, the presence of catalase, and the pattern of sugar fermentation (Table 1). Strains of *H. influenzae* and *H. parainfluenzae* can be subdivided into biotypes based on biochemical reactions that determine the presence of urease and ornithine decarboxylase, and the production of indole (Table 2). Strains of *H. influenzae* can be further classified according to their polysaccharide capsule. There are a total of six structurally and antigenically distinct capsular types (referred to as serotypes), designated a through f (Table 3). In addition, strains can be nonencapsulated, as defined by their failure to react with typing antisera to all capsular serotypes, and are considered nontypeable. Most type b isolates are biotype I, whereas the majority of nontypeable strains are biotype II or III.

In recent years, multilocus enzyme electrophoresis has been employed to examine isolates of *H. influenzae*. Studies with this technique have demonstrated that the population structure of encapsulated *H. influenzae* is clonal, with most isolates falling into a few common clonal groups (Musser et al., 1990; Musser et al., 1988). Nontypeable strains are genetically distinct and are more heterogeneous compared

Table 1. Differential characteristics of *Haemophilus* species.

Organism	X factor required	V factor required	Hemolysis of horse blood	Catalase	Fermentation of							
					Glucose	Fructose	Sucrose	Lactose	Xylose	Ribose	Mannose

VIII	IV	–	–	–

Symbols: +, present; –, absent.

Table 3. Structures of *H. influenzae* capsular polysaccharides.^a

Type	Structure
a	4)-β-D-Glc-(1 → 4)-D-ribitol-5-(PO ₄ →
b	3)-β-D-Rib-(1 → 1)-D-ribitol-5-(PO ₄ →
c	4)-β-D-GlcNAc-(1 → 3)-α-D-Gal-1-(PO ₄ → 3 OAc
d	4)-β-D-GlcNAc-(1 → 3)-β-D-ManANAc-(1 → 6 R = serine, threonine, or alanine. R
e	3)-β-D-GlcNAc-(1 → 4)-β-D-ManANAc-(1 →
e'	3)-β-D-GlcNAc-(1 → 4)-β-D-ManANAc-(1 → 3 β-D-fructose
f	3)-β-D-GalNAc-(1 → 4)-α-D-GalNAc-1-(PO ₄ → 3 OAc

Abbreviations: Glc, glucose; Gal, galactose; GlcNAc, *N*-acetyl glucosamine; and ManANAc, *N*-acetyl-D-mannosamine.

^aRibose and fructose are in the furanose ring form; Glc, Gal, GlcNAc, and ManANAc are in the pyranose ring form.

with encapsulated *H. influenzae* (Musser et al., 1986).

Isolation and Identification

Haemophilus species are facultative anaerobes and have both a respiratory and a fermentative type of metabolism. They catabolize D-glucose and other carbohydrates, producing acids and sometimes gas. They are non-motile and non-spore-forming. In addition, they are oxidase positive and reduce nitrates to nitrites or beyond. For most species, growth is optimal at a temperature of 33–37°C in a humid environment.

Haemophilus species that require factor X are lacking the enzymes necessary for conversion of δ-aminolevulinic acid (ALA) to protoporphyrin IX, the penultimate intermediate in the heme biosynthesis pathway (Biberstein et al., 1963). In

most cases, the requirement for factor X can be satisfied by supplementation of culture media with purified protoporphyrin IX. An active ferrochelatase, which catalyzes ferrous iron insertion into the protoporphyrin nucleus to form heme, has been demonstrated in a panel of *H. influenzae* strains, and this enzyme is presumed to be present in any *Haemophilus* strain that is able to use protoporphyrin IX as the sole source of factor X (Loeb, 1995). Although few isolates depend on pre-formed heme for growth, typically blood or blood derivatives, such as crystalline hemin, are used as the source of factor X for cultivation of *Haemophilus*. Hemin requirements generally range from 0.1 to 10 µg/ml for *H. influenzae* (Biberstein and Spencer, 1962; Brumfitt, 1959; Evans et al., 1974; Gilder and Granick, 1947) but can be as high as 200 µg/ml for optimal growth of *H. ducreyi* (Hammond et al., 1978).

Determination of a requirement for factor X is easily accomplished using the porphyrin test (Kilian, 1974), in which a large loopful of bacteria is inoculated into 0.5 ml of 0.1 M sodium phosphate buffer, pH 6.9, containing 0.08 mM magnesium sulfate and 2 mM δ -ALA and then incubated at 37°C for 4 hours. Factor X-independent bacteria incorporate the ALA into the heme biosynthesis pathway and excrete pathway intermediates, such as porphobilinogen and porphyrins. These intermediates emit a red fluorescence and can be detected by examination under a Wood's light (360 nm) in a dark room. Factor X-dependent bacteria lack the enzymes needed for production of these intermediates and do not excrete them.

The requirement for factor V is usually satisfied by supplementation of culture media with purified crystalline nicotinamide adenine dinucleotide (NAD), with alternatives including NAD phosphate (NADP) and nicotinamide mononucleoside. Typical NAD requirements range from 0.2 to 1 μ g/ml for *H. influenzae* and from 1 to 5 μ g/ml for *H. parainfluenzae*, although some strains exhibit requirements as high as 25 μ g/ml. When NAD-deficient agar media are used for the isolation of bacteria from sites of mixed microbial populations that include *Haemophilus*, small colonies of NAD-dependent *Haemophilus* organisms are often observed growing around larger colonies of other bacterial species, such as *Staphylococcus aureus* or *Pseudomonas aeruginosa*. This phenomenon is referred to as satellitism and arises from the ability of factor V-dependent *Haemophilus* colonies to utilize NAD secreted by other bacteria. In an application of this phenomenon, a plate previously streaked with *Haemophilus* is cross-inoculated with a single streak of the "feeder" (NAD-producing) organism. Growth of factor V-dependent *Haemophilus* strains is initially confined to the areas immediately adjacent to the feeder streak but eventually extends peripherally as the NAD diffuses through the agar. NAD-impregnated sterile paper disks can be used in place of cross-inoculation to demonstrate factor V-dependent satellitism.

Although the blood in sheep blood agar contains both NAD and hemin, NAD-degrading enzymes also present in the blood make this medium unsuitable for cultivation of most *Haemophilus* species. Instead, *Haemophilus* has historically been grown on chocolate agar, which is made by adding 5–10% defibrinated blood to sterilized blood agar base and holding the mixture at 80°C for 15 to 20 minutes, until the medium turns a dark brown color reminiscent of chocolate. This heating process both liberates NAD from the red blood cells and inactivates NAD-degrading enzymes, although it also results

in degradation of some of the NAD. A more uniform medium is obtained with "enriched" chocolate agar, in which factor V is provided as a constituent of a chemically defined supplement (either Isovital X or supplement B) and factor X is provided from an artificial "hemoglobin" preparation consisting of washed and lysed red blood cells. A 2% solution of the "hemoglobin" preparation is autoclaved and added to an equal volume of sterilized double-strength GC medium base (a standard medium consisting of proteose peptone/corn starch/phosphate salts) after both solutions have cooled to 50°C. Isovital X or supplement B is then added to a final concentration of 1% to complete the preparation.

Owing to its opacity, chocolate agar is less than optimal for certain applications, including visual screening of clinical specimens and laboratory strains for capsule production. Transparent plates made from supplemented brain heart infusion agar (BHIs agar) represent an alternative. Brain heart infusion agar is a commercially available rich medium that is autoclaved and then supplemented with a 1:1000 dilution of NAD stock solution (2 mg/ml β -NAD dissolved in water and filter sterilized) and one of several hemin sources, including purified crystalline hemin, clarified defibrinated horse blood, or Fildes extract (a commercially available peptic digest of blood). Another source of hemin is Levinthal's stock, which is prepared by boiling a mixture of 35% horse blood in autoclaved BHI broth and removing the particulate clotted matter by filtration through sterile filter paper or by centrifugation. Plates containing 2% Levinthal's stock traditionally contain a relatively high concentration of NAD, in the range of 10 μ g/ml. Clarified defibrinated horse blood and Fildes extract are generally preferred over Levinthal's stock because they are simpler to prepare. A solution of crystalline hemin is also relatively simple to prepare but results in plates with a shorter shelf life. Growth of *Haemophilus* in liquid culture is best accomplished in BHIs broth, which is prepared in the same manner as BHIs agar, except for omission of the agar.

Aside from the requirement for rich media supplemented with hemin and NAD, some *Haemophilus* species and occasional unusual isolates require special additional nutrients or alterations in growth conditions. For example, *H. ducreyi* grows well only on chocolate agar containing 5–10% fetal bovine serum (Nsanze et al., 1984; Sottnek et al., 1980) and grows optimally at a temperature of 33°C, compared to 35–37°C for other *Haemophilus* species (Sturm and Zanen, 1984). In addition, rare strains of *H. influenzae* require supplemental pantothenic acid, thiamine, uracil, or specific nucleotides for optimal growth (Evans and Smith, 1972; Holt, 1962). As

another example, it appears that increased CO₂ tension is a requirement for optimal growth and in some cases for any growth for many *Haemophilus* species, especially those whose names are derived from the Greek term “aphros,” referring to carbon dioxide bubbles produced by fermenting wine (*H. aphrophilus*, *H. paraphrophilus* and *H. paraphrohaemolyticus*). The metabolic basis for this supposed CO₂ dependence is not known, and in many of these organisms, an observed loss of CO₂ dependence upon subculture has cast doubt on the absolute nature of this requirement (Kilian, 1976; Zinnemann et al., 1971). One possibility is that the atmospheric effects of increased CO₂ tension actually serve to fulfill a growth requirement for increased ambient moisture, a hypothesis supported by the successful cultivation of several “CO₂-dependent” strains of *H. influenzae* and *H. aphrophilus* in a moist environment lacking CO₂ (Hoiseth, 1992; Kraut et al., 1972). Nevertheless, a moist environment containing 5–10% CO₂ is generally recommended for cultivation of *Haemophilus* isolates (Albritton, 1989; Kilian, 1976).

Preservation

Following growth on agar plates or in broth culture, *Haemophilus* strains remain viable for only a few days when stored at room temperature. *Haemophilus* species are not amenable to prolonged storage at 4°C either. Consequently, the preferred method for long-term storage involves deep freezing at temperatures below –70°C. Bacteria are prepared for deep freezing by swabbing growth from an agar plate into 2-ml cryovials containing brain heart infusion broth (or another suitable growth medium, such as heart infusion broth or Levinthal’s stock) supplemented with 10–20% sterile glycerol. Alternatively, broth cultures can be inoculated and grown to mid-log phase (OD₆₀₀ = 0.3–0.4), then transferred to cryovials containing glycerol, again aiming for a final concentration of 10–20% glycerol. As another option, strains can be stored in skim milk. Survival of *Haemophilus* at ambient temperatures is sufficient to allow short-term (1 to 3 days) transport of cultures either streaked onto chocolate agar or BHIs agar plates, which are then sealed with parafilm, streaked onto chocolate agar or BHIs agar slants, or inoculated into sealed plastic vials or glass ampoules containing BHIs broth or another suitable growth medium.

Habitat and Ecology

Haemophilus species are members of the normal flora in the upper respiratory tract and occasion-

ally the genital area and gastrointestinal tract. *Haemophilus influenzae*, *H. parainfluenzae*, *H. haemolyticus*, *H. parahaemolyticus*, *H. paraphrohaemolyticus*, *H. aphrophilus*, *H. paraphrophilus* and *H. segnis* are found in the pharynx in healthy humans. *Haemophilus parainfluenzae*, *H. haemolyticus*, *H. parahaemolyticus*, *H. aphrophilus*, *H. paraphrophilus* and *H. segnis* are found in the oral cavity as well, and *H. aphrophilus*, *H. paraphrophilus*, *H. segnis* and *H. haemolyticus* also are often present in dental plaque and gingival scrapings. *Haemophilus influenzae* and *H. parainfluenzae* have occasionally been isolated from the urethra and vagina in women. *H. ducreyi* is primarily a genital pathogen in humans. Among animal species, *H. paragallinarum* is a member of the normal respiratory flora in fowl, *H. parasuis* is found in the respiratory tract of pigs, *H. paracuniculus* is present in the gastrointestinal tract of rabbits, and *H. haemoglobinophilus* forms part of the normal flora of the preputial sac of dogs. *Haemophilus somnus* occupies the respiratory tract and the genital tract of cattle, while the reservoir for *H. agni* is presumed to be a mucosal surface in sheep.

Physiology

Heme and Iron Acquisition

The requirement for heme in factor X-dependent *Haemophilus* species presents a challenge for the proliferation of these organisms during natural infection. Free heme is toxic to mammalian cells and is sequestered within the body by the carrier protein hemopexin. Hemoglobin, another usable source of heme in the human body, is sequestered by the carrier protein haptoglobin. To acquire heme from the host environment, factor X-dependent *Haemophilus* species express several multicomponent systems devoted to the efficient binding and uptake of heme from heme : hemopexin and hemoglobin : haptoglobin sources. Although these systems were first identified and characterized in several strains of *H. influenzae* type b, similar mechanisms have also been shown to exist in nontypeable *H. influenzae* and to some extent in *H. ducreyi*.

One system involved in binding heme : hemopexin complexes in *H. influenzae* consists of the proteins HxuA, HxuB and HxuC, which are all expressed from a single operon encompassing the *hxuA*, *hxuB* and *hxuC* genes (Cope et al., 1995; Hanson et al., 1992a). The 100-kDa HxuA protein is released from the bacterial surface into the culture supernatant, where it binds heme : hemopexin (Cope et al., 1998; Cope et al.,

1994). The 60-kDa HxuB protein mediates release of HxuA from the cell surface. The 78-kDa HxuC protein is thought to assist in transfer of bound heme into the bacterial cell because it is similar to TonB-dependent outer membrane proteins. TonB is an energy-transducing cytoplasmic membrane protein that facilitates a variety of transport processes via its interactions with members of a family of outer membrane proteins (Postle, 1990). The role of TonB in heme uptake and its importance in vivo were demonstrated by the inability of *tonB* mutants to utilize heme : hemopexin and by the reduced virulence of these mutants in an infant rat model of bacteremia (Jarosik et al., 1994). Mutation of either *tonB* or *hxC* also results in an inability to grow on low levels of free heme, suggesting that these proteins are involved not only in the uptake of heme from heme:hemopexin complexes but also in the uptake of free heme (Cope et al., 1995; Jarosik et al., 1994). A second *H. influenzae* system involved in heme : hemopexin binding consists of a 57-kDa heme : hemopexin outer membrane receptor and two accessory proteins, including a 29-kDa outer membrane protein and the P2 outer membrane porin. Assembly of this complex is regulated by ambient levels of iron (Wong et al., 1994; Wong et al., 1995). Distinct heme binding properties in *H. influenzae* have also been associated with a 61-kDa lipoprotein encoded by *hbpA* and an iron-regulated 39.5-kDa outer membrane protein (Hanson et al., 1992b; Lee, 1992).

A number of different proteins capable of binding hemoglobin and hemoglobin : haptoglobin have been identified in *H. influenzae* (Frangipane et al., 1994). The first to be characterized was HgpA, a 120-kDa protein that is encoded by the *hgpA* gene and is expressed in response to conditions of limited heme availability (Jin et al., 1996; Jin et al., 1999). HhuA, a 115-kDa homologue of HgpA identified in a different *H. influenzae* strain, has also been shown to bind hemoglobin:hemopexin (Maciver et al., 1996). Like HxuC, HgpA and HhuA exhibit similarity to the TonB-dependent family of outer membrane proteins. Interestingly, mutation of *hgpA* in *H. influenzae* strain HI689 did not restrict growth with hemoglobin or hemoglobin : haptoglobin, and subsequent characterization of this mutant led to the discovery of two additional hemoglobin-binding proteins encoded by separate genes, designated *hgpB* and *hgpC* (Morton et al., 1999; Ren et al., 1998). These proteins are 115 kDa and 120 kDa, respectively, and both are highly homologous to HgpA. Expression of either HgpA, HgpB or HgpC is both necessary and sufficient to support growth with hemoglobin or hemoglobin:haptoglobin. Further analysis of the genes encoding these proteins in several

different strains revealed the presence of CCAA nucleotide repeats in the 5'-coding sequence, suggesting that expression of these proteins is subject to phase variation by a slipped-strand mispairing mechanism (Cope et al., 2000; Ren et al., 1999). Given the high degree of sequence similarity between HgpA, HgpB, HgpC and HhuA, it is likely that these proteins represent homologues that are expressed in different strains and have been duplicated in some instances. Of note, a homologue of HgpA has been identified in *H. ducreyi* strain 35000, and expression of this hemoglobin-binding protein is critical for virulence in human volunteer studies (Al-Tawfiq et al., 2000; Elkins, 1995a; Elkins et al., 1995b).

Similar to the situation with heme, elemental iron is toxic to mammalian cells and is therefore sequestered by the host. Proteins that sequester iron include transferrin, lactoferrin and ferritin. Levels of free iron in the body are maintained far below those required for survival and growth of microorganisms (Otto et al., 1992). Unlike a number of other bacteria, *Haemophilus* species have not been reported to secrete siderophores, soluble proteins capable of binding free iron or iron complexed with host proteins (Morton and Williams, 1990; Weinberg, 1978). Instead, many *Haemophilus* species rely on a complex system of proteins that engage in specific binding of transferrin at the bacterial cell surface, removal of iron from transferrin, and transport of free iron into the cell (Hardie et al., 1993; Herrington and Sparling, 1985; Schryvers, 1988; Schryvers, 1989; Schryvers and Gray-Owen, 1992). As with the systems for heme uptake, for the most part, the proteins involved in iron acquisition by *Haemophilus* were identified first in *H. influenzae*, including type b and nontypeable strains. Interestingly, *H. influenzae* can bind transferrins from human, bovine and rabbit sources but not from several other mammalian species (Herrington and Sparling, 1985; Morton and Williams, 1990; Schryvers, 1988; Schryvers, 1989), perhaps accounting in part for the host specificity of this organism. Similarly, the bovine pathogen *H. somnus* binds bovine transferrin selectively, and the porcine pathogen *H. parasuis* binds porcine transferrin preferentially (Charland et al., 1995; Ogunnariwo et al., 1990).

During the process of *H. influenzae* acquisition of iron from transferrin, two outer membrane proteins are responsible for binding transferrin at the bacterial cell surface. Transferrin-binding protein 1 (Tbp1) is a 95-kDa integral membrane protein encoded by *tbpA*, and Tbp2 is a lipid-anchored variable size protein, ranging from 68 to 85 kDa, encoded by *tbpB* (Gray-Owen and Schryvers, 1995a; Gray-Owen et al., 1995b; Stevenson et al., 1992). Both Tbp1 and

Tbp2 are capable of binding transferrin and are expressed as a single transcriptional unit under the control of a ferric uptake regulatory (Fur-like) repressor protein (Gray-Owen and Schryvers, 1995a). Expression of Tbp1 and Tbp2 in vivo is supported by RT-PCR analysis of samples from patients with otitis media (Whitby et al., 1997) and by reactivity of these proteins with sera obtained from healthy adults (Holland et al., 1992; Holland et al., 1996). Based on the predicted amino acid sequence, Tbp1 is presumed to be a TonB-dependent protein, a conclusion supported by the observation that inactivation of *tonB* eliminates the ability of *H. influenzae* to utilize iron from transferrin (Jarosik et al., 1995). Although mutation of either *tbpA* alone or both *tbpA* and *tbpB* together eliminates utilization of iron from transferrin, mutation of *tbpB* alone is permissive for the utilization of transferrin, provided transferrin is present in high concentration (Gray-Owen and Schryvers, 1995a). With this information in mind, one hypothesis is that Tbp2 extends from the bacterial surface and binds transferrin, thereby increasing the effective concentration of transferrin at the cell surface and facilitating interaction with Tbp1. Tbp1, in turn, initiates the TonB-dependent release of iron and the transport of free iron into the periplasm (Rao et al., 1999).

Subsequent transfer of iron from the periplasmic space into the cytoplasm relies on proteins encoded by the *hitA*, *hitB* and *hitC* genes, which are located on a single 4-kb operon regulated by a Fur-like repressor (Adhikari et al., 1995; Sanders et al., 1994). The *hitA* gene encodes FbpA, a periplasmic high-affinity iron-chelating protein that belongs to the transferrin superfamily and is essential for iron uptake (Bruns et al., 1997; Kirby et al., 1997). The *hitB* gene encodes a cytoplasmic membrane permease (HitB), and *hitC* encodes a nucleotide binding protein (HitC). Presumably, free iron in the periplasm is bound by FbpA and transferred to HitB, which then actively transports the iron into the cytoplasm in a step energized by HitC.

Sugar Metabolism

In light of the small genomes and fastidious growth requirements of *Haemophilus* species, it is not surprising that these organisms employ relatively simple pathways for sugar metabolism. Based on biochemical and genetic information, *Haemophilus* species appear to utilize the Embden-Meyerhof-Parnas, the hexose monophosphate and the Entner-Duodoroff pathways, and the tricarboxylic acid cycle (Fleischmann et al., 1995; Holländer, 1976a; Klein, 1940; White, 1966). Glycolytic metabolism in the absence of

an oxidative electron transport chain has been observed only in selected factor X-dependent species of *Haemophilus*, including *H. influenzae* and *H. haemoglobinophilus* (White, 1963). Extensive biochemical analysis of one strain of *H. parainfluenzae* suggests that in species capable of oxidative sugar catabolism, glycolysis occurs only in the presence of a terminal electron acceptor, such as oxygen, nitrate or fumarate (White, 1966; White and Sinclair, 1971). Electron transfer in these species proceeds from flavoproteins via cytochromes *b*, *c*, *d* and *a* to demethylmenaquinone (DMK), to cytochrome *o*, and finally to an oxygen or nitrate terminal electron acceptor (Holländer, 1976b; White and Sinclair, 1971). Most *Haemophilus* species appear to use DMK as the sole respiratory quinone. In *H. haemolyticus*, *H. haemoglobinophilus*, *H. parvus* and *H. paragallinarum*, ubiquinone is present as well (Holländer et al., 1981; Holländer and Manheim, 1975).

In *H. influenzae*, fructose appears to play a central role in sugar metabolism. Fructose uptake by *H. influenzae* occurs via a phosphoenolpyruvate:carbohydrate phosphotransferase system (PTS) that phosphorylates fructose as it is transported across the cytoplasmic membrane. In other Gram-negative bacteria, the PTS serves as both transport machinery and sensor for a number of preferred sugar substrates (Postma et al., 1993). Limitations in the availability of these preferred sugars results in a backup of the phosphotransferase enzymes, which initiates increased cAMP production by adenylate cyclase and subsequent cAMP-receptor protein (CRP)-mediated transcriptional activation of genes involved in the uptake and catabolism of other sugar substrates (Botsford and Harman, 1992). Genetic and biochemical analysis has demonstrated that the PTS of *H. influenzae* is specific for fructose, unlike the situation with other Gram-negative organisms (Macfadyen et al., 1996b). In the absence of available fructose, *H. influenzae* upregulates transport and catabolism of galactose, ribose, xylose and fucose. Additionally, *H. influenzae* imports and catabolizes glycerol, glucose and sialic acid in a PTS-independent manner.

Several facets of *H. influenzae* sugar metabolism deserve further comment. In particular, at first glance the central role of fructose is difficult to understand given the limited availability of this sugar in the human upper respiratory tract, the usual habitat of *H. influenzae*. However, it is possible that a preference for fructose serves *H. influenzae* in two separate ways: first, it may prevent *H. influenzae* from having to compete for glucose with host cells and other commensal bacteria; second, it may be advantageous to rapid proliferation of bacteria during invasion of the

cerebrospinal fluid, where fructose concentrations are 30-fold higher than serum levels (Macfadyen and Redfield, 1996a). In addition, it is interesting that *H. influenzae* utilizes sialic acid. This sugar is readily available in the respiratory tract as a terminal component of branched chain oligosaccharides on glycoproteins found on the surfaces of epithelial cells, in mucus and in serum. Although *H. influenzae* possesses many of the enzymes necessary for uptake and catabolism of sialic acid (Casari et al., 1995; Vimr et al., 2000), a gene encoding the neuraminidase necessary for liberating sialic acid from oligosaccharides is conspicuously absent from the *H. influenzae* Rd genome. However, neuraminidase activity has been reported in selected *H. influenzae* isolates (Muller and Hinz, 1977), and strains that lack a neuraminidase may be dependent on the neuraminidase activity of other respiratory commensal organisms or pathogens, such as *Pseudomonas aeruginosa* (Macfadyen and Redfield, 1996a). Neuraminidase activity is also seemingly absent in *H. somnus* and *H. aphrophilus* but has been demonstrated in *H. parausis* and *H. paragallinarum* (Hinz and Muller, 1977; Lichtensteiger and Vimr, 1997). Of further note, *H. influenzae* appears to express a constitutively active nucleoside uptake system and a PTS-dependent competence induction system. Thus, natural competence may serve a second, non-genetic purpose of providing bacteria with an energetically efficient source of nucleotides from a mucosal environment rich in DNA (Lethem et al., 1990; Matthews et al., 1963) but limited in energy substrates required during de novo nucleotide synthesis (Macfadyen and Redfield, 1996a).

Genetics

Haemophilus influenzae is a naturally transformable organism and readily takes up DNA from its environment. Transformation of this organism was observed as early as 1951 when Alexander and Leidy reported that capsule production could be restored in nonencapsulated R variants of each of the six *H. influenzae* capsular serotypes after exposure to DNA isolated from encapsulated donor strains (Alexander and Leidy, 1951). Additional studies demonstrated that strain Rd (derived from a serotype d strain) was most efficient among the tested strains at transformation with DNA from representatives of all capsular serotypes (Alexander et al., 1954), and this strain has since become the workhorse of *Haemophilus* genetic analysis and manipulation. Such efforts have been greatly enhanced by the publication of the 1.83-Mb Rd genome in 1995 (Fleischmann et al.,

1995), the very first genome of a cellular organism to be sequenced in its entirety. The Rd genome and emerging sequence information for the genome of *H. ducreyi* strain 35000 can be accessed through the website of {The Institute for Genomic Research}.

Although mechanisms and applications of genetic manipulation are most extensively described for *H. influenzae* strain Rd, transformation has been used with great success for manipulation of clinical isolates of both encapsulated and nontypeable *H. influenzae* and other *Haemophilus* species as well, including *H. parainfluenzae*, *H. ducreyi*, *H. parausis*, *H. paragallinarum* and *H. somnus* (Gonzales et al., 1996; Gromkova and Goodgal, 1979; Sanders et al., 1997; Stevens et al., 1995). As with the *H. influenzae* R variants, variation in transformation efficiency exists both across and within *Haemophilus* species. For example, a recent study examining transformation efficiencies of clinical isolates of *H. parainfluenzae* found that biotype II strains were highly transformable, while biotype I and biotype III strains were relatively refractory to transformation (Gromkova et al., 1998). Similarly, transformation efficiency varies considerably from one strain of *H. influenzae* to another, with some strains being nontransformable (Rowji et al., 1989).

Early work demonstrated successful transformation of a number of *Haemophilus* species with both intraspecific and interspecific *Haemophilus* DNA (Beattie and Setlow, 1970; Leidy et al., 1959; Leidy et al., 1956; Leidy et al., 1965; Schaeffer, 1958; Steinhardt and Herriott, 1968; White et al., 1964). Subsequent studies showed that transformation of *Haemophilus* species occurs much more efficiently with DNA from *Haemophilus* than with DNA from bacteria of other genera (Danner et al., 1982b; Goodgal and Mitchell, 1984; Kahn and Smith, 1984; Mathis and Scocca, 1982; Scocca et al., 1974; Sisco and Smith, 1979). In the case of *H. influenzae*, this preference is a consequence of the mechanism of DNA uptake by naturally competent organisms, a process that involves specific recognition of a nine base pair sequence (AAGTGCGGT) within the transforming DNA by receptors present on the bacterial cell surface (Deich and Smith, 1980). This uptake sequence is common throughout the *H. influenzae* chromosome but is generally rare or absent in non-*Haemophilus* DNA. In the 1.83-Mb genome of *H. influenzae* strain Rd, the uptake sequence occurs at 1,465 sites, with an average distance of 1,224 bp between two such sites (Smith et al., 1999). Interestingly, the sites occur more often in intergenic regions of the chromosome than in coding sequence, and the existence of multiple pairs of uptake sequences in inverted repeat orientations suggests that

these pairs may form stem-loop structures that act as transcriptional terminators.

The cellular receptors to which *Haemophilus* DNA uptake sequences bind are components of membranous blebs termed "transformasomes," which appear on the cell surface during induction of competency (Barany et al., 1983; Kahn et al., 1983). After binding to *H. influenzae* transformasomes, DNA passes into the bacterial cell via a process that results in the complete degradation of one DNA strand and partial degradation of the other strand, termed the "entering strand" (Barany et al., 1983). The bacterial chromosome is somehow accessible to DNA within the transformasome, and degradation of the entering strand ceases once it finds a homologous site within the chromosome and becomes incorporated by *rec*-dependent recombination. DNA entry into *H. parainfluenzae* cells involves a somewhat different set of events with far less degradation of DNA within the transformasome (Barany and Kahn, 1985). Transformation of *Haemophilus* with stable plasmids is thought to depend on the low frequency accidental escape of plasmid DNA from the transformasome (Pifer, 1986). Maintenance of a stable plasmid is also dependent on the absence of recombination between plasmid and chromosomal DNA, and for this reason, recombination-deficient strains, such as the DB117 *recA* isogenic mutant of *H. influenzae* Rd, are usually used as recipients for transformation of plasmids.

Although *Haemophilus* is naturally competent, only about one cell in ten thousand is capable of DNA uptake during exponential growth. However, competence can be induced in an entire population by conditions of slowed growth that occur during nutrient deprivation or transient anaerobiosis, leading to transformation efficiencies as high as 1–5%. The mechanisms that underlie competence induction, DNA uptake, and DNA integration in *Haemophilus* constitute a genetically programmed response to such growth conditions. These mechanisms have been studied most extensively in *H. influenzae* strain Rd. Competence induction in response to nutrient deprivation is dependent on a functioning fructose-specific phosphoenolpyruvate:carbohydrate phosphotransferase system (PTS), a multi-enzyme component of the bacterial sugar import machinery (Gwinn et al., 1996; Macfadyen et al., 1996b). Sensing of sugar availability by the PTS acts in concert with a cellular cAMP phosphodiesterase to modulate levels of cellular cAMP, which presumably regulates expression of competence-associated genes via cAMP receptor protein (CRP)-mediated transcriptional activation (Macfadyen et al., 1998). Examination of mutant strains defective in competence induction or DNA uptake has identified a number of

essential genes involved in these processes. These include genes encoding a periplasmic disulfide oxidoreductase (*por*) homologous to *dsbA* of *Escherichia coli*, a type IV pilin-like protein biogenesis operon, several drug efflux transporters, a phospholipid biosynthesis enzyme, and several loci encoding genes of unknown function (Beattie and Setlow, 1971; Dougherty and Smith, 1999; Gwinn et al., 1998; Larson and Goodgal, 1991; Redfield, 1991; Tomb, 1992; Tomb et al., 1989).

Over the years, several methods have been developed to transform *Haemophilus* (Goodgal and Herriott, 1961; Herriott et al., 1970; Stuy, 1962). In experiments with *H. influenzae*, the M-IV method is most efficient and involves incubation of early log-phase bacteria in defined minimal medium, then exposure to transforming DNA, and then overnight outgrowth on selective medium (see Barcak et al., 1991 for details). This protocol results in transformation rates of $\sim 10^7$ transformants per ml of competent cells exposed to 1 μ g of chromosomal DNA. A second method developed in *H. influenzae* involves overnight growth of bacteria in a small volume of a complex liquid medium that contains transforming DNA, then selection on solid medium (see Barcak et al., 1991 for details). The growth conditions used to achieve natural transformation in *H. influenzae* result in a substantial loss of viability when applied to *H. parainfluenzae* (Barany and Kahn, 1985). As a consequence, *H. parainfluenzae* is transformed instead by a method that involves overnight incubation of a small volume of bacteria in a stationary Petri dish (Gromkova and Goodgal, 1979). Efficient transformation of *H. influenzae*, *H. ducreyi* and *H. somnus* has been accomplished by methods developed for enteric bacteria, including electroporation (Dower et al., 1988) and the calcium chloride (CaCl_2) method (Barcak et al., 1991; Sanders et al., 1997; Stevens et al., 1995).

Owing to the complex nutritional requirements of *Haemophilus* species, auxotrophic markers have not been used for selection of transformants. On the other hand, antibiotic resistance markers have been used extensively. A number of plasmid cloning vectors incorporating a variety of antibiotic resistance genes have been constructed for the purpose of *Haemophilus* genetic manipulation. Many of these plasmids are able to serve as shuttle vectors between *Haemophilus* and *E. coli* because they contain origins of replication for both organisms (Table 4). The first such vector to be described was pHVT1, which carries the *Haemophilus* pRSF0885 origin of replication (*ori*) along with ampicillin and tetracycline resistance genes (Danner and Pifer, 1982a). This plasmid has spawned a number of derivatives containing

Table 4. *H. influenzae* cloning vectors.

Abbreviations and working concentrations (µg/ml) for selectable markers in *H. influenzae*: Ap, Ampicillin (2–10); Cm, Chloramphenicol (2); Km, Kanamycin (25–50); Sm, Streptomycin (250); Sp, Spectinomycin (15); Su, sulfonamides; Tc, Tetracycline (5–10).

^aPlasmids carrying only the pRSF0885 ori are capable of replication in both *H. influenzae* and *E. coli*.

^bThe p15A ori is capable of directing replication in both *E. coli* and *H. influenzae*.

^cThe *N. gonorrhoeae* pJD5 ori of pFP10 is capable of directing replication in *H. influenzae*, *H. ducreyi*, and *E. coli*.

^dpLS88 was isolated from *H. ducreyi* and is also capable of replicating in *H. influenzae* and *E. coli*.

additional unique restriction sites and other antibiotic resistance markers (Barcak et al., 1991). Additional cloning vectors have been described that also use the pRSF0885 ori but contain either different antibiotic selection markers or different *E. coli* origins of replication (McCarthy et al., 1982; Trieu and McCarthy, 1990). Several *Haemophilus* cloning vectors containing origins of replication distinct from that of pRSF0885 have also been described. One example is pLS88, which was originally isolated from *H. ducreyi*. This plasmid carries resistance markers for sulfonamides, streptomycin and kanamycin (Dixon et al., 1994; Willson et al., 1989). Plasmids carrying the *E. coli* P15A replication origin, including pQL1, pACYC184, pACYC177, pSU2718 and pSU2719, are also able to replicate in *Haemophilus* (Barcak et al., 1991; Heidecker et al., 1994). Recently Pagotto et al. described a panel of vectors that contain a *Neisseria gonorrhoeae* ori and are capable of replicating in *Neisseria*, *Haemophilus* and *E. coli* (Pagotto et al., 2000). In addition to the introduction of stable plasmids and site-directed mutagenesis by insertional inactivation, transformation of various transposon elements conferring kanamycin resistance into *H. influenzae*, *H. ducreyi* and *H. paragallinarum* has been successfully employed for random insertion mutagenesis (Gonzales et al., 1996; Gwinn et al., 1997; Kauc and Goodgal, 1989; Kraiss et al., 1998; Stevens et al., 1995).

In contrast to the ease of transformation, other methods of genetic manipulation such as phage transduction and conjugation have not

been well established in *Haemophilus*. Four different bacteriophages have been identified in isolates of *H. influenzae*, although none appears to be useful for transduction (Boling et al., 1973; Stuy, 1978). Conjugation pili have not been identified in any *Haemophilus* species, and low frequency conjugal transfer of chromosomal genes by *H. influenzae* has been reported only once, in a system that utilized an *E. coli* F' plasmid (Deich and Green, 1987). Thus, transformation remains the mainstay of *Haemophilus* genetic manipulation.

Epidemiology and Pathogenesis of Disease

H. influenzae

Historically, *H. influenzae* type b has accounted for over 95% of invasive *H. influenzae* disease. A combination of non-type b encapsulated strains and nontypeable strains have accounted for the remaining cases. Non-type b encapsulated strains are especially important in developing countries. As an example, among children in Papua New Guinea, approximately 25% of lower respiratory tract isolates and 15% of cerebrospinal fluid (CSF) isolates of *H. influenzae* are non-type b encapsulated strains, especially type a and type f (Gratten and Montgomery, 1991; Lehmann, 1992).

Before the implementation of routine immunization against *H. influenzae* type b in devel-

oped countries, this organism was the leading cause of bacterial meningitis and epiglottitis in children younger than 5 years, accounting for 10,000 to 12,000 cases per year in the United States in the mid-1980s. *Haemophilus influenzae* type b was also a major cause of septic arthritis, pneumonia, pericarditis and facial cellulitis among young children. In the 1980s, approximately 1 in 200 children in the United States experienced invasive *H. influenzae* type b disease before the age of 5 years, with the peak incidence occurring between six months and two years of age (Cochi et al., 1985). Disease was most prevalent in boys, African Americans, Alaskan Eskimos, Apache and Navajo Indians, day care center attendees, and children living in overcrowded conditions. Pre-existing medical conditions such as sickle cell anemia, asplenia, human immunodeficiency virus (HIV) infection, certain immunodeficiency syndromes, and malignancies were important predisposing factors for *H. influenzae* type b systemic infection. Over the past 10 years, the incidence of invasive *H. influenzae* type b disease in developed countries has fallen dramatically (Rosenstein and Perkins, 2000). This decline has occurred even in regions where rates of immunization against *H. influenzae* type b are well below 100%, reflecting unexpected herd immunity related to decreased rates of carriage (Centers for Disease Control and Prevention, 1998a). Currently, only 100 to 300 cases of invasive *H. influenzae* type b disease are reported in the United States each year, mostly in non-vaccinated or under-vaccinated children, particularly in Native American communities where carriage rates remain high (Bisgard et al., 1998; Galil et al., 1999).

Despite the successful reduction of invasive *H. influenzae* type b disease in industrialized countries, *H. influenzae* type b remains an important pathogen in developing countries, where routine immunizations are still not available to most of the population. In these countries, *H. influenzae* type b remains the leading cause of bacterial meningitis and the second leading cause of bacterial pneumonia, resulting in up to 500,000 deaths per year in children younger than five years of age (Levine et al., 1998). A recent meta-analysis of *H. influenzae* type b-related medical reports from 75 countries estimated that vaccine usage by a total of 38 countries has resulted in just a 5.7% worldwide decrease in *H. influenzae* type b-related meningitis and less than a 2% worldwide decrease in all *H. influenzae* type b-related diseases, including pneumonia (Peltola, 2000). These figures reflect the current lack of vaccine availability in approximately 175 countries, most notably populous nations in Asia and Africa, where upwards of 118 million children remain unvaccinated (Children's Vaccine Initiative, 1999).

Nontypeable *H. influenzae* is present in the upper respiratory tract of 40–80% of healthy children and adults (Ingvarson et al., 1982; Kilian et al., 1972; Kuklinska and Kilian, 1984). Although nontypeable strains usually exist as commensal organisms in the nasopharynx, they are also an important cause of localized respiratory tract disease. In children, these organisms are the most common cause of purulent conjunctivitis, the second most common cause of otitis media (after *Streptococcus pneumoniae*), a frequent cause of acute and chronic sinusitis, and an important cause of exacerbations of cystic fibrosis (Gilligan, 1991). Among children in developing countries, nontypeable strains are a common cause of pneumonia and a significant source of mortality (Monto, 1989). In adults, nontypeable *H. influenzae* is a common cause of community-acquired pneumonia, otitis media, sinusitis, and exacerbations of underlying lung disease, including chronic bronchitis and bronchiectasis (Kilbourn et al., 1983).

Nontypeable *H. influenzae* is also an occasional cause of serious systemic disease such as septicemia, endocarditis, meningitis and septic arthritis. In individuals with bacteremia, abnormalities in humoral immunity are especially common, with examples including hypogammaglobulinemia, acquired immunodeficiency syndrome (AIDS), lymphoproliferative disease and acute leukemia. Meningitis accounts for a high percentage of nontypeable *H. influenzae* invasive disease, especially in children under 5 years of age. In most cases, meningitis develops as a complication of a CSF leak or by direct extension from a contiguous focus of infection, such as otitis media or sinusitis. During the past two decades nontypeable *H. influenzae* has become recognized as a cause of early-onset neonatal sepsis that occurs most often in premature infants and is acquired from the maternal urogenital tract (Friesen and Cho, 1986; Stull et al., 1988). Several studies indicate that many of these neonatal isolates are members of a cryptic biotype IV genospecies that is not common at other sites of infection and appears to be a genetically distinct *Haemophilus* species (Quentin et al., 1989; Quentin et al., 1996).

Because of the worldwide prevalence of *H. influenzae* disease, this organism has been the subject of intense laboratory investigation. A wealth of information relating to the molecular mechanisms of *H. influenzae* disease pathogenesis has emerged, and these mechanisms are described in detail in a number of excellent review articles (Foxwell et al., 1998; Moxon, 1992; Murphy, 2000; Rao et al., 1999; St. Geme, 1997). Several animal models of *H. influenzae* disease exist, including rat and chinchilla models of otitis media, a mouse pulmonary clearance

model, and an infant rat model of bacteremia and meningitis (Green et al., 1994; Hansen and Toews, 1992; Moxon et al., 1977; Yang et al., 1998a). However, these models fail to reproduce all aspects of natural disease, reflecting the fact that *H. influenzae* is a human-specific pathogen. Accordingly, much of our knowledge about interactions between *H. influenzae* and the human host has come from in vitro studies employing human adenoid and nasal turbinate tissue in organ culture, primary human respiratory epithelial cells, and cultured human cell lines.

Spread of *H. influenzae* occurs via inhalation of airborne droplets or by direct contact with respiratory tract secretions from an infected individual. Colonization of the new host is facilitated by pilus and non-pilus adhesins, which promote intimate interaction between bacteria and the respiratory mucosa, including respiratory epithelium and mucus. Both type b and selected nontypeable strains express hemagglutinating pili, which were first identified based on their ability to mediate bacterial attachment to human oropharyngeal epithelial cells and agglutination of human erythrocytes (Guerina et al., 1982; Pichichero et al., 1982; Stull et al., 1984). The proteins responsible for pilus biogenesis are encoded by a cluster of five genes designated *hifA-hifE* and include a major structural subunit (HifA), a periplasmic chaperone (HifB), an outer membrane usher (HifC), a nucleating structural subunit (HifD), and a pilus tip adhesin (HifE) (Rao et al., 1999). *Haemophilus influenzae* pili probably interact with sialyllactosylceramide on host epithelial cells, as compounds containing this structure are able to inhibit both hemagglutination and pilus-mediated attachment to epithelial cells (van Alphen et al., 1991). In addition, pili have been shown to promote bacterial adherence to respiratory mucins and to the heparin-binding domain of fibronectin (Kubiet et al., 2000; Virkola et al., 2000).

Approximately 75–80% of nontypeable strains express high-molecular-weight non-pilus adhesins referred to as HMW1 and HMW2, which are highly related to each other and share homology with filamentous hemagglutinin, an adhesin and colonization factor expressed by *Bordetella pertussis* (Barenkamp and Leininger, 1992; St. Geme et al., 1998). Overall, the predicted amino acid sequences of HMW1 and HMW2 are 71% identical and 80% similar. Despite their homology, these proteins exhibit different cellular binding specificities, suggesting that they interact with distinct receptor structures and may serve complementary functions in the process of colonization (Dawid et al., 2001; Hultgren et al., 1993). Experiments with HMW1 have demonstrated that this adhesin recognizes

a glycoprotein receptor containing N-linked oligosaccharide chains with sialic acid in an α -2-3 configuration (St. Geme, 1994a). At this point, the HMW2 receptor remains poorly characterized. Expression of both HMW1 and HMW2 is controlled by the number of 7-bp repeats present in the promoter region of the structural gene, with the number of repeats varying via slipped-strand mispairing and influencing transcription (Dawid et al., 1999).

Among nontypeable strains that lack HMW adhesins, almost all express an alternative non-pilus adhesin called Hia (Barenkamp and St. Geme, 1996b; St. Geme et al., 1998). The Hia protein is a member of the growing family of autotransporter proteins, which includes the *N. gonorrhoeae* and *H. influenzae* IgA1 proteases and a number of other Gram-negative bacterial proteins implicated in virulence (Henderson et al., 1998). Autotransporters employ a distinctive mechanism of secretion, with the C-terminal domain of the protein forming a β -barrel porin in the outer membrane and facilitating translocation of the rest of the protein, called the passenger domain, to the cell surface. *Haemophilus influenzae* type b strains express a ~240-kDa homologue of Hia called Hsf. In experiments with cultured epithelial cells, Hia and Hsf confer the same adhesive specificities, suggesting that the *hia* and *hsf* genes are alleles of the same locus (St. Geme et al., 1996). Overall, Hia and Hsf share 72% identity and 80% similarity. The two proteins are most similar at their N-terminal and C-terminal ends and also contain a conserved internal domain that is repeated three times in Hsf, thus accounting in part for the difference in size (St. Geme et al., 1996). One hypothesis is that the larger size of Hsf reflects the need for the adhesive domain to extend beyond the confines of the type b capsule.

Nearly all nontypeable *H. influenzae* strains express a 155-kDa protein called Hap which was first discovered based on its ability to promote bacterial entry into epithelial cells (St. Geme et al., 1994b). In addition, Hap promotes adherence to a variety of cultured epithelial cells (St. Geme et al., 1994b). Like Hia, Hap is an autotransporter protein and consists of a C-terminal β -barrel domain (called Hap β) and an internal passenger domain (called Hap ς). Hap ς contains the adhesive activity of the protein and also possesses serine protease activity that mediates the autoproteolytic cleavage of Hap ς from Hap β and subsequent release of Hap ς from the cell surface (Hendrixson et al., 1997). Of interest, interactions between Hap ς molecules retained on the cell surface result in bacterial aggregation and microcolony formation. Hap autoproteolytic activity is blocked by secretory leukocyte protease inhibitor (SLPI), a compound that is

present in normal respiratory secretions and is upregulated during states of inflammation (Hendrixson and St. Geme, 1998). One hypothesis is that local concentrations of SLPI may modulate the amount of Hap_s retained on the cell surface, thus influencing patterns and levels of bacterial association with respiratory epithelial tissue and spread of bacteria through the respiratory tract. As another possibility, the serine protease activity of Hap_s may be important for degradation of host proteins involved in structural integrity of respiratory epithelium or the immune response.

In recent work, several additional adhesive activities have been identified in *H. influenzae*. Using thin layer chromatography, Busse et al. found that type b and nontypeable strains are capable of recognizing phosphatidylethanolamine (PE), gangliotriosylceramide (Gg3), gangliotetrosylceramide (Gg4), sulfatoxygalactosylceramide, and, to a lesser extent, sulfatoxygalactosylglycerol (Busse et al., 1997). To extend this observation, these investigators prepared a phosphatidylethanolamine affinity matrix and purified a 46-kDa protein that inhibits binding of whole bacteria to immobilized PE and Gg3. More recently, Hartmann and Lingwood reported that heat shock treatment resulted in a marked increase in binding by nontypeable *H. influenzae* to sulfatoxygalactosylceramide (Hartmann and Lingwood, 1997). Additional analysis suggested that this binding is due to two Hsp70-related heat shock proteins. In studies with respiratory tract mucins, Reddy and co-workers reported that outer membrane proteins called P2 and P5 promote appreciable binding (Reddy et al., 1996). Lipooligosaccharide (LOS) is another molecule that influences interactions with host cells, recognizing platelet activating factor (PAF) receptor and facilitating both adherence and invasion (Swords et al., 2000). Studies by Prasadarao and coworkers indicate that OapA is an additional protein involved in adherence (Prasadarao et al., 1999). OapA is a surface-associated protein responsible for the transparent-colony phenotype in both encapsulated and nonencapsulated *H. influenzae* and is required for efficient colonization in the infant rat nasopharyngeal colonization model (Weiser et al., 1995).

Successful colonization of the respiratory tract by *H. influenzae* requires that bacteria circumvent the mucociliary escalator. Respiratory viral infection, exposure to cigarette smoke and other environmental agents, and inherited ciliary structure abnormalities influence the ability of *H. influenzae* to overcome mucociliary clearance. Based on experiments with human nasopharyngeal tissue in organ culture, *H. influenzae* can disrupt mucociliary function directly, inducing ciliostasis and extrusion of ciliated epithelial cells

(Read et al., 1991; Read et al., 1992; Wilson et al., 1996). Ciliotoxic activity has been attributed to the lipid A moiety of its LOS, to peptidoglycan fragments, and to an immunoglobulin-binding glycerophosphodiesterase called protein D (Janson et al., 1999; Johnson and Inzana, 1986; Kanthakumar et al., 1996). Of note, mutation of protein D results in reduced virulence in a rat model of otitis media, supporting the potential role of this protein in altering ciliary function (Janson et al., 1994).

Persistence of *H. influenzae* on the respiratory mucosa during colonization and in the bloodstream during invasive disease requires that the organism evade the host immune response. The polysaccharide capsule of encapsulated *H. influenzae* protects these bacteria against antibody binding, complement deposition and phagocytosis in nonimmune hosts. A region of the chromosome referred to as "the *cap* locus" controls expression of the capsule in all encapsulated *H. influenzae*. This locus consists of four serotype-specific genes that encode enzymes involved in biosynthesis of the polysaccharide subunit, a set of upstream genes devoted to the export of subunits (*bexA-bexD*), and a group of downstream genes that influence surface assembly of the capsule (Kroll and Booy, 1996). The genetic structure of the *cap* locus facilitates the frequent duplication or loss of this locus via homologous recombination, and the number of *cap* locus copies present in an organism correlates directly with the amount of capsule produced (Roche and Moxon, 1995). Though it may seem disadvantageous for encapsulated *H. influenzae* to readily lose their capsule, it has been shown that loss of capsule results in a marked increase in the ability of bacteria to associate with epithelial cells (St. Geme and Falkow, 1992; St. Geme and Falkow, 1991a). Thus, diminished encapsulation may be an important early step during respiratory tract colonization, a step that is somehow reversed during invasion into the bloodstream.

Another factor presumed to play an important role in immune evasion is the *H. influenzae* IgA₁ protease, which is homologous to the IgA₁ proteases expressed by *N. gonorrhoeae* and *N. meningitidis*. This extracellular endopeptidase cleaves the hinge region in both the serum and secretory forms of IgA₁ and releases the antigen-binding Fab domains from the Fc portion of the molecule, thus eliminating agglutination activity (Plaut, 1978). *Haemophilus influenzae* IgA₁ protease is specific for IgA₁ of humans and higher primates (Qiu et al., 1996) and does not cleave IgA₂ of any species, owing to distinct sequence differences between the hinge regions of IgA₁ and IgA₂. Two types of *H. influenzae* IgA₁ proteases exist: type 1 proteases cleave the peptide bond between the proline at position 231 and the

serine at position 232, and type 2 proteases cleave the peptide bond between the proline at position 235 and the threonine at position 236 (Kilian et al., 1980; Mulks et al., 1980). Most *H. influenzae* strains produce either one or both types of IgA₁ protease (Insel et al., 1982; Kilian and Thomsen, 1983a; Kilian and Thomsen, 1983b; Male, 1979; Mulks et al., 1982). Many investigators have speculated that the IgA₁ protease is critical for the pathogenesis of *H. influenzae* disease. However, despite the widespread expression of this potential virulence factor in pathogenic *Haemophilus* species and its absence in nonpathogenic species (Senior and Ip, 1999), there is no direct evidence demonstrating its importance in the pathogenic process.

Haemophilus influenzae invasion into respiratory epithelium has been proposed as another important mechanism by which the organism evades the host immune response. Microscopic examination of human adenoid tissue and cultured respiratory epithelial cells infected with nontypeable *H. influenzae* suggests that organisms enter respiratory epithelial cells and also pass between cells into deeper tissue via a process called "paracytosis" (Forsgren et al., 1994; van Schilfgaarde et al., 1995). In addition, *H. influenzae* has been reported to reside inside macrophages inhabiting respiratory epithelial tissue (Forsgren et al., 1996). Cellular invasion and paracytosis may provide an explanation for the observation that occasionally the same strain of nontypeable *H. influenzae* persists despite antibiotic treatment. Studies to define the molecular determinants of paracytosis are currently underway (van Schilfgaarde et al., 2000).

Recent studies of *H. influenzae* LOS biosynthesis suggest that the addition of phosphorylcholine (ChoP) may be important to *H. influenzae* persistence in the respiratory tract. LOS production is controlled by three genetic loci, called *lic1*, *lic2*, and *lic3*. Addition of ChoP to LOS is controlled by the *lic1* locus and is phase variable, because of the presence of intragenic CAAT tandem nucleotide repeats in the first gene of this locus, *licA* (Weiser et al., 1997). Surface expression of ChoP decreases bacterial susceptibility to an antimicrobial peptide expressed in the upper respiratory tract

(Lysenko et al., 2000a) and promotes persistence in an infant rat model of nasopharyngeal carriage (Weiser et al., 1998). However, surface expression of ChoP may also be disadvantageous to bacteria because it is the target of C-reactive protein (CRP)-mediated serum bactericidal activity (Lysenko et al., 2000b; Weiser et al., 1998).

The first vaccines against *H. influenzae* type b were developed in the 1970s and consisted of polyribosylribitol phosphate (PRP; the type b polysaccharide) by itself. These plain polysaccharide vaccines were used with success among children over 24 months of age in Finland and parts of the United States and Canada (American Academy of Pediatrics Committee on Infectious Diseases, 1985; Anderson et al., 1972). Unfortunately, these vaccines were poorly immunogenic in children younger than 24 months and had little influence on nasopharyngeal carriage rates (Makela et al., 1977; Peltola et al., 1984; Takala et al., 1991). These problems were addressed in the late 1980s by the development of conjugate vaccines that consisted of PRP bound covalently to an immunogenic carrier protein. Currently, four conjugate vaccines are commercially available, all differing with respect to the size of the polysaccharide, the chemical linkage between the polysaccharide and the carrier protein, and the specific carrier protein employed (see Table 5). As a result of these structural differences, each of the conjugate vaccines has slightly different immunogenic properties, in some cases influencing the recommended immunization schedule. All four vaccine preparations are well tolerated and can be administered at the same physician visit as other vaccines.

In contrast to the situation with *H. influenzae* type b, no vaccine is available for the prevention of disease due to nontypeable *H. influenzae*. Development of such a vaccine has been the subject of intense efforts over the past decade. Among the major challenges along these lines is the identification of an antigen that is highly conserved among diverse strains of nontypeable *Haemophilus* and is also immunogenic. Current candidates include the major outer membrane proteins called P4, P5 and P6, an outer membrane protein called OMP26, the HMW, Hia and

Table 5. *H. influenzae* type b conjugate vaccines licensed for use in children.

Vaccine	Trade name	Polysaccharide	Linkage	Protein carrier	Licensed for Infants ^a
PRP-OMP	PedvaxHIB	Medium	Thioether	<i>N. meningitidis</i> outer membrane protein complex	Yes
HbOC	HibTITER	Small	None	CRM ₁₉₇ (a nontoxic diphtheria toxin)	Yes
PRP-T	ActHIB/OmniHIB	Large	6-Carbon	Tetanus toxoid	Yes
PRP-D	ProHIBit	Medium	6-Carbon	Diphtheria toxoid	No

^aAge < 15 months.

Hap adhesins, and Tbp2 (Akkoyunlu et al., 1991; Barenkamp, 1996a; El-Adhami et al., 1999; Green et al., 1994; Kodama et al., 2000; Nelson et al., 1991; Webb and Cripps, 1999; Webb and Cripps, 2000). In addition, in recent studies LOS conjugates and whole cell preparations have been examined for their vaccine potential (Foxwell and Cripps, 2000; Sun et al., 2000).

H. INFLUENZAE BIOGROUP AEGYPTIUS *Haemophilus influenzae* biogroup aegyptius represents a distinct subgroup of *H. influenzae* biotype III that is characteristically associated with purulent conjunctivitis. Koch first isolated this organism in 1883 from the eyes of Egyptian children with conjunctival infection (Koch, 1883). Three years later Weeks reported isolation of the same organism from American patients with acute conjunctivitis (Weeks, 1886). As a consequence, *H. influenzae* biotype aegyptius is also known as the Koch-Weeks bacillus. Further studies by Weeks demonstrated that the organism could be transmitted from patients to human volunteers and was responsible for epidemics of conjunctivitis (Weeks, 1887; Weeks, 1895). In the twentieth century, cases of *H. influenzae* biogroup aegyptius conjunctivitis in the United States have been limited to the southern states, particularly during warmer months (Bengston, 1933; Davis and Hines, 1952; Davis and Pittman, 1950). Nevertheless, a 1981 study found that this organism was the most common cause of acute purulent conjunctivitis in children over one month of age (Gigliotti et al., 1981). Although the eye gnat (*Hippelates pusio*) might be an important vector of transmission during epidemics of conjunctivitis (Buehler et al., 1983), *H. influenzae* biogroup aegyptius is also responsible for sporadic conjunctival infection, presumably resulting from direct person-to-person transmission.

In addition to causing acute purulent conjunctivitis, *H. influenzae* biogroup aegyptius causes Brazilian purpuric fever (BPF), a fulminant bacteremic disease of young children first recognized in 1984 in rural Brazil (Brazilian Purpuric Fever Study Group, 1987a; Brazilian Purpuric Fever Study Group, 1987b). Brazilian Purpuric Fever is characterized by fever, abdominal pain, vomiting, rapid progression to purpura, and vascular collapse, with death in approximately 60% of cases. Patients with BPF are typically between the ages of 3 months and 10 years, with the peak incidence occurring between 1 and 4 years. Often the onset of BPF is preceded by an episode of purulent conjunctivitis, suggesting that this illness results from systemic spread of bacteria from an initial site of localized infection.

In 1986, isolates of *H. influenzae* biogroup aegyptius recovered from ten Brazilian children with BPF were subjected to extensive analysis,

including protein profiles, multilocus enzyme electrophoresis, ribosomal RNA gene restriction mapping, plasmid restriction mapping, and seroagglutination reactions. This analysis established that all strains were members of the same clone and distinct from other strains of *H. influenzae* biogroup aegyptius (Brenner et al., 1988). Organisms isolated from two Australian patients with symptoms consistent with BPF were also shown to be *H. influenzae* biogroup aegyptius, but these strains were distinct from the BPF clone identified in Brazil (McIntyre et al., 1987).

Although little is known about the pathogenic mechanisms by which BPF strains cause such serious disease, a number of insights have emerged. First, these strains express both pilus and nonpilus adhesins, which presumably facilitate mucosal colonization (St. Geme et al., 1991b). Second, Porto and colleagues found that BPF strains are relatively serum resistant, which may account in part for their ability to survive in the bloodstream (Porto et al., 1989). Third, BPF strains are cytotoxic for microvascular endothelial cells, a property that possibly underlies the purpura and vascular collapse that occur during BPF (Weyant et al., 1994). Finally, examination of individuals living in areas endemic for BPF shows that young children generally lack serum bactericidal activity against BPF, while most older children and adults have high titers of bactericidal antibodies (Rubin et al., 1993). This observation may provide at least a partial explanation for the age-related incidence of BPF.

H. ducreyi

Haemophilus ducreyi is the etiologic agent of chancroid, a sexually transmitted disease characterized by painful genital ulceration and inguinal lymphadenitis. Chancroid is a common cause of genital ulcers in developing countries, but in the United States, it is generally confined to outbreaks in economically disadvantaged minority communities (Schmid et al., 1987). *H. ducreyi* infection is often associated with co-infection by other sexually transmitted pathogens such as *Treponema pallidum* or herpes simplex virus, and chancroid has been shown to be an important cofactor in transmission of HIV (Centers for Disease Control and Prevention, 1998b; Wasserheit, 1992).

Transmission of *H. ducreyi* occurs during sexual contact with an infected person and involves introduction of the organism into a break in the genital epithelium. After an incubation period of four to seven days, a papule develops at the site of infection. The papule then evolves into a pustule over the next two to three days and eventually ruptures spontaneously to form a sharply circumscribed ulcer. Multiple ulcers may appear

and then resolve, with some ulcers occasionally coalescing to form giant ulcers. Roughly 50% of chancroid patients also develop inflamed inguinal lymph nodes, which often become fluctuant and rupture spontaneously. Based on polymerase chain reaction (PCR) studies, asymptomatic carriage of *H. ducreyi* has been reported in female prostitutes but has not been observed in males (Hawkes et al., 1995).

Accurate diagnosis of chancroid relies on cultivation of *H. ducreyi* from the lesion using proper media (synthetic chocolate agar containing 5% fetal bovine serum and 3 µg/ml of vancomycin) and incubation conditions (33°C in a humid, CO₂-enriched environment). Gram stain of material swabbed from the lesion typically shows characteristic Gram-negative bacteria in a "school of fish" configuration; however, the presence of other bacteria can confound interpretation.

Although the precise mechanism of *H. ducreyi* colonization remains unclear, research over the past decade has identified several potential *H. ducreyi* colonization factors. Virtually all clinical isolates express fine tangled pili with a superstructure distinct from pili of other bacteria (Brentjens et al., 1996). Although experiments to date have been unable to demonstrate that *H. ducreyi* pili possess adhesive activity (Bauer and Spinola, 1999; Frisk and Lagergard, 1998a), it is likely that these organelles promote bacterial interaction with host cells and facilitate colonization. Many strains of *H. ducreyi* also express high molecular weight proteins called LspA1 and LspA2, which are homologous to *B. pertussis* filamentous hemagglutinin (Ward et al., 1998). The absence of these proteins in four strains that are avirulent in a rabbit model of chancroid suggests that they may contribute to colonization. In addition, the *H. ducreyi* GroEL heat shock protein is present on the bacterial surface and appears to promote interbacterial interactions or bacteria-host cell interactions (Frisk et al., 1998b; Parsons et al., 1997).

Tissue damage during genital ulcer formation is likely to involve both bacterial and host factors. One bacterial factor that may play a role in this process is a toxin that was identified based on the ability of *H. ducreyi* to induce distension and delayed cytotoxicity in cultured epithelial cells (Cope et al., 1997). This toxin is referred to as cytolethal distending toxin (CDT) and is composed of three proteins, encoded by genes called *cdtA*, *cdtB* and *cdtC*. Of note, CDT is a member of a family of toxins produced by a variety of Gram-negative pathogens, in all cases inducing similar effects in epithelial cells. CDT cytotoxic activity apparently arises from induction of cell cycle arrest at the G2 phase in target cells (Cortes-Bratti et al., 1999). Experimental evi-

dence suggests that CDT may serve to inhibit the host immune response by inducing apoptosis in T cells (Gelfanova et al., 1999). Interestingly, despite these in vitro observations, comparison of a wild-type strain and an isogenic CDT mutant revealed no difference in virulence in the rabbit experimental infection model (Stevens et al., 1999). Another protein that may influence tissue damage is a cell-associated hemolysin called HhdA, which is capable of lysing cultured human epithelial cells and fibroblasts (Alfa et al., 1996; Palmer and Munson, 1995; Totten et al., 1995; Wood et al., 1999). However, similar to the situation with CDT, a mutant deficient in production of hemolysin and in vitro cytolytic activity remained fully virulent in the rabbit model (Palmer et al., 1998).

In considering the determinants of *H. ducreyi* persistence within genital epithelium, several recent observations provide some insight. In particular, Al-Tawfiq and co-workers found that inactivation of the *hgbA* gene eliminated *H. ducreyi* hemoglobin binding and resulted in reduced pustule formation and bacterial recovery in human volunteers, underscoring the importance of heme acquisition (Al-Tawfiq et al., 2000). In addition, Elkins et al. discovered a variable size outer membrane protein called DsrA, which mediates resistance to killing by normal serum antibody and complement and presumably plays a key role in *H. ducreyi* survival (Elkins et al., 2000).

Efforts to develop a vaccine for the prevention of chancroid have relied on the rabbit infection model to examine the protective effect of immunization with *H. ducreyi* preparations, including whole cell lysates, cell envelopes, purified pili and purified hemolysin (HhdA; Desjardins et al., 1996; Dutro et al., 1999; Hansen et al., 1994). Some degree of success has been reported in each of these vaccination studies, but commercial vaccine production for use in humans will require much additional work.

Other Human Isolates

The species *H. parainfluenzae*, *H. parahaemolyticus*, *H. paraphrohaemolyticus*, *H. segnis*, *H. aphrophilus* and *H. paraphrophilus* are members of the normal flora in the upper respiratory tract and oral cavity. These organisms can cause local or systemic disease, especially in the setting of a compromised immune system. Besides *H. influenzae*, *H. parainfluenzae* represents the most common pathogen among human *Haemophilus* species and has been reported in association with pharyngitis, otitis media, conjunctivitis, dental abscess, epiglottitis, pneumonia, empyema, septicemia, septic arthritis, osteomyelitis, peritonitis, hepatobiliary infection, meningitis, brain abscess,

epidural abscess, and urinary tract and genital infection. Both *H. aphrophilus* and *H. paraphrophilus* have been associated with a similar spectrum of diseases, along with rare instances of cervical lymphadenitis, lumbar spondylitis, paraspinal abscess and intracranial abscess (Hart et al., 1998; Hung et al., 1997; Margelli and Streit, 1996; Samuel et al., 1997; White et al., 2000). Serious disease in association with *H. aphrophilus* is exceedingly rare in individuals who are immunocompetent and otherwise healthy, but several such cases have been reported, including meningitis complicated by hydrocephalus and humeral shaft osteomyelitis following routine dental work (Adeyemi-Doro et al., 1998; Dewire et al., 1999). *Haemophilus parainfluenzae*, *H. aphrophilus* and *H. paraphrophilus* also have a predilection to cause endocarditis, typically in patients with pre-existing congenital or rheumatic heart disease. Together, these organisms account for approximately 5% of cases of infectious endocarditis and may have been responsible for a portion of "culture-negative" endocarditis reported in the past (Geraci et al., 1977).

A curious association between *H. parainfluenzae* infection and IgA nephropathy has been reported in Japan (Suzuki et al., 1998). Examination of kidney biopsy samples from Japanese children and adults revealed *H. parainfluenzae* antigens in the renal mesangium in patients with IgA nephropathy but not in patients with other renal diseases (Ogura et al., 2000; Suzuki et al., 1994). In addition, sera from patients with IgA nephropathy contained significantly higher levels of IgA reactive with *H. parainfluenzae* antigens than did sera from control patients. Furthermore, tonsillar mononuclear cells from patients with IgA nephropathy were found to be more reactive to *H. parainfluenzae* antigens than were cells from a control group of patients with chronic tonsillitis, producing significantly higher levels of TGF- β , IL-10, and *H. parainfluenzae*-specific IgA (Suzuki et al., 2000a; Suzuki et al., 2000b). Finally, intraperitoneal infection of mice with *H. parainfluenzae* resulted in renal deposition of immune complexes containing bacterial antigen and in pathological changes similar to those observed human IgA nephropathy (Yamamoto and Suzuki, 1999). The relevance of these findings to the pathogenesis of IgA nephropathy in Japan and around the world will require further evaluation.

Haemophilus segnis is a common resident of dental plaque and gingival scrapings, and the presence of this organism has been correlated with severe periodontal lesions (Petsios et al., 1995). Additionally, *H. segnis* has been associated with rare cases of cholecystitis, appendicitis, pancreatic abscess, and endocarditis (Bangsberg

et al., 1988; Bullock and Devitt, 1981; Carson et al., 1997; Namnyak et al., 1991). Both *H. parahaemolyticus* and *H. paraphrohaemolyticus* have been associated with acute pharyngitis, mouth ulcers, and rare cases of endocarditis. *Haemophilus haemolyticus* has not been associated with any disease.

A recent study examined a collection of *Haemophilus* isolates for IgA1 protease activity. This study detected IgA1 protease production in only one of three *H. parahaemolyticus* strains and in none of the *H. aphrophilus*, *H. paraphrophilus*, *H. segnis* and *H. paraphrohaemolyticus* strains tested (Senior and Ip, 1999). It is interesting to speculate that the relative lack of pathogenicity of the oral *Haemophilus* species may be due in part to the absence of this virulence factor, which is commonly produced by isolates of *H. influenzae*.

Animal Isolates

Haemophilus paracuniculus has been isolated from the gastrointestinal tracts of rabbits with mucoid enteritis (Targowski and Targowski, 1979). However, the pathogenic potential of this organism is unknown, as it appears in the context of a generalized pathologic response of the colon to constipation (Sinkovics, 1976).

Haemophilus haemoglobinophilus is part of the normal flora of the preputial sacs of dogs. It has been isolated from dogs with suppurative inflammation of the prepuce (Rivers, 1922), but its identity as the etiologic agent of this particular infection has never been established. Several reports also exist of *H. haemoglobinophilus* associated with human infections. In one case, it was isolated from the middle ear of an agammaglobulinemic child with otitis media (Frazer and Rogers, 1972). In another instance, it was isolated from a boy who had contracted osteomyelitis following a dog bite (Lavine et al., 1974).

Haemophilus somnus is an inhabitant of the respiratory and genital tracts of healthy cattle, but like *H. influenzae*, it also can cause disease in its host. In addition to cattle, *H. somnus* has also been isolated from bison and sheep (Ward et al., 1999; Ward et al., 1995). This organism is one of a large group of bacterial and viral agents of bovine respiratory disease (BRD), which encompasses a range of pathologic infectious processes, including bronchiolitis, pneumonia and bronchopneumonia. Additionally, *H. somnus* can cause invasive disease, such as arthritis, bacteremia and meningoencephalitis. The occurrence of *H. somnus* disease is an issue of worldwide importance. The clinical significance of this organism is exemplified by a large-scale Canadian study of feedlot calves, which found that over a three-year period, *H. somnus* infection

accounted for more than 40% of mortality from BRD (Van Donkersgoed et al., 1994a). Furthermore, a study of feedlot calves in Denmark found that *H. somnus* was most often associated with the most severe cases of respiratory disease, such as fibronecrotizing bronchopneumonia (Tegtmeier et al., 1999). Clinical manifestations of *H. somnus* urogenital infections include vesicular adenitis in beef bulls, abortion, and "weak calf syndrome" resulting from perinatal transmission of the organism (Chladek, 1975; Grote-lueschen et al., 1994; Waldhalm et al., 1974). Management of bovine hemophilosis is accomplished with the long-acting antibiotic oxytetracycline, which significantly reduces mortality of BRD but has not been shown to be an effective prophylactic agent (Van Donkersgoed et al., 1994a). Efforts at vaccine development have focused on killed whole organisms, detoxified lipid A, and preparations of unique outer membrane antigens (Groom and Little, 1988; Inzana and Todd, 1992; Silva and Little, 1990; Van Donkersgoed et al., 1995; Van Donkersgoed et al., 1994b). Although many of these agents elicit strong immune responses, none has proven effective enough at preventing disease to warrant use on a large scale.

Several potential virulence factors contributing to *H. somnus* pathogenesis have been described, including a family of high molecular weight peripheral outer membrane Fc (immunoglobulin) receptors that may help this organism evade the bovine immune response in the same manner that protein A contributes to *Staphylococcus aureus* pathogenesis in humans (Corbeil et al., 1997). These immunoglobulin-binding proteins (IgBPs) strongly bind bovine IgM, IgA and IgG2b (Batista et al., 1999; Yarnall et al., 1988). The importance of these proteins in pathogenesis is further supported by their absence in four serum-sensitive isolates from asymptomatic carriers (Cole et al., 1993; Cole et al., 1992). Another property of *H. somnus* that presumably contributes to virulence is the ability to survive within and subvert the defense systems of bovine macrophages. Populations of viable and replicating *H. somnus* have been observed in membrane-bound vacuoles of blood monocytes and alveolar macrophages isolated from experimentally infected cattle. Stimulation of these macrophages with lipopolysaccharide (LPS) or bovine cytokines, such as TNF- α , IL-1 β and IFN- γ , reduced but did not eliminate intracellular bacteria (Gomis et al., 1998). This observation may be explained in part by the ability of *H. somnus* cultures to inhibit nitric oxide production by bovine blood monocytes and alveolar macrophages in vitro (Gomis et al., 1997). Finally, examination of *H. somnus* interaction with bovine polymorphonuclear leukocytes in vitro

suggests that this organism may inhibit neutrophil phagocytosis and respiratory burst and may even induce neutrophil apoptosis (Pfeifer et al., 1992; Yang et al., 1998b).

H. parasuis is a member of the normal flora of the respiratory tracts of pigs but also can cause symptomatic respiratory infections and polyserositis (Glässer's disease). Clinical symptoms of *H. parasuis* infection include neurological signs, anorexia, lameness, swollen joints, difficulty in breathing, fever, wasting, lethargy, cyanosis, and unilateral ear inflammation. More severe manifestations include abortion and even sudden death. In the United States and Canada, *H. parasuis* disease is associated mainly with two antigenic serotypes (more than fifteen serotypes have been documented), with four additional serotypes and nontypeable strains accounting for the majority of remaining cases (MacInnes and Desrosiers, 1999). In addition to LPS, potential virulence factors of *H. parasuis* include a species-specific transferrin-binding protein (Charland et al., 1995) and a neuraminidase (Lichtensteiger and Vimr, 1997).

Haemophilus paragallinarum is the etiologic agent of infectious coryza in chickens, a disease of worldwide economic importance. Infection of poultry stocks by this organism has resulted in significant mortality in North and South America, Argentina, India, Morocco, South Africa and Thailand. Symptoms of infectious coryza include nasal discharge, facial swelling, lacrimation, anorexia and diarrhea. Concurrent infection by a variety of other pathogens is associated with more complicated, invasive disease that can include arthritis, septicemia, and spread of *H. paragallinarum* to nonrespiratory sites such as kidney, liver and tarsus (Sandoval et al., 1994). The *H. paragallinarum* isolates from healthy and diseased hosts are typically classified into three antigenic serogroups, and all three serogroups have been implicated in disease. Commercial vaccines against *H. paragallinarum* based on a combination of killed organisms representing each of the three serogroups are widely available around the world. However, local variations in the prevalence of certain serovars within each of the serogroups, and the emergence of new serovar variants in some regions, continue to be an obstacle to international vaccine efficacy.

The Genus *Pasteurella*

HENRIK CHRISTENSEN AND MAGNE BISGAARD

Introduction

Members of the bacterial genus *Pasteurella* usually are regarded as opportunistic, secondary invaders in vertebrates. *Pasteurella multocida* is the only representative of the genus regarded as a major pathogen. Most taxa represent opportunistic invaders that might inhabit the mucosal membranes of the upper respiratory and lower genital tracts of mammals and birds. For most taxa, the pathogenic potential is unknown. The genus *Pasteurella* includes nine named species (*P. multocida*, *P. canis*, *P. stomatis*, *P. dagmatis*, *P. gallinarum*, *P. avium*, *P. volantium*, *P. langaa* and *P. anatis*) and two unnamed taxa (*Pasteurella* species A and species B), all referred to as *Pasteurella* sensu stricto. The type species of the genus *P. multocida* has been separated into three subspecies, *P. multocida* subsp. *multocida*, *P. multocida* subsp. *gallicida* and *P. multocida* subsp. *septica*. In addition, excluding seven species of *Pasteurella* (*[P.] aerogenes*, *[P.] pneumotropica*, *[P.] trehalosi*, *[P.] caballi*, *[P.] mairii*, *[P.] bettyae* and *[P.] testudinis*) from *Pasteurella* has been suggested; however, their names have not been formally changed and the genus name of these species is consequently denoted in brackets. General reference is made to *Pasteurella* sensu stricto.

Phylogeny

The phylogeny of the genus *Pasteurella* has been investigated by 16S rRNA sequence comparison and rRNA-DNA hybridization (DeLey et al., 1990; Dewhirst et al., 1992; Dewhirst et al., 1993; Olsen et al., 2003). The phylogenetic position of members of *Pasteurella* is shown by analysis of the 16S rRNA sequences of well characterized strains of Pasteurellaceae; however, it remains to be demonstrated that these strains also represent the genetic core of the respective taxa. Thirteen monophyletic groups were recognized in addition to ten taxa not belonging to any group (Fig. 1). Except for the position of “Testudinis” as an out-group, the relative order of these groups and

of the single taxa not included in groups could not be determined. The type species *P. multocida* and the species *P. canis*, *P. stomatis*, *P. dagmatis*, and the unnamed taxon *Pasteurella* species B form the monophyletic core-group of *Pasteurella* sensu stricto (cluster 3B of Dewhirst et al. [1993] and cluster 12 of Olsen et al. [2003]). The two subspecies *multocida* and *gallicida* of *P. multocida* have identical 16S rRNA sequences, and only the sequence of the type strain of *P. multocida* was included in the analysis. The close phylogenetic relationship between the three subspecies of *P. multocida* and *P. canis* has been confirmed by phylogenetic analysis of the *atpD* gene sequence (Petersen et al., 2001a). The avian species, *P. gallinarum*, *P. avium*, *P. volantium* and *Pasteurella* species A, form a separate monophyletic group (cluster 3A of Dewhirst et al., 1993) along with the type strain of *[Haemophilus] paragallinarum* (the brackets indicate that the species is not a true member of genus *Haemophilus*; Mutters et al., 1989). The species *[H.] paragallinarum* is described in The Genus in this Volume *Haemophilus*, but it is phylogenetically related to *Pasteurella* sensu stricto (see also Kilian, 2003). *[Haemophilus] paragallinarum* was not included in the phylogenetic analysis because of its incomplete 16S rRNA sequence.

Also, 16S rRNA sequence comparison showed that *P. langaa* and *P. anatis* were phylogenetically unrelated both to the core group and to the avian group of *Pasteurella*. This is in accordance with previous investigations (Dewhirst et al., 1992; Dewhirst et al., 1993; Olsen et al., 2003). *Pasteurella anatis* was proposed to be included in the new genus *Gallibacterium* (Christensen et al., 2003a), and *P. langaa* was found to be related to *[P.] caballi* by 16S rRNA phylogenetic analysis (Fig. 1). The seven species suggested to be excluded from the genus were scattered on the phylogenetic tree of Pasteurellaceae (Fig. 1). *[Pasteurella] pneumotropica* biotype Jawetz was included in a monophyletic group with other rodent-associated taxa (Dewhirst et al., 1993; Olsen et al., 2003; Fig. 1). *[Pasteurella] aerogenes* was found to be polyphyletic with one group including the type strain being related to *[P.]*

Fig. 1. Maximum likelihood phylogenetic analysis of the bacterial family Pasteurellaceae based on 16S rRNA gene sequence comparison (Olsen et al., 1994) including variable outgroup comparisons and bootstrap analysis. Monophyly for individual groups including support from bootstrap analysis have been marked by bold lines. Members of *Pasteurella* sensu stricto have been typed in green whereas members of the taxa excluded from *Pasteurella* have been typed in red. The naming and numbering of monophyletic groups has been adopted from Olsen et al. (2003).

mairii (Fig. 1), while the other was related to [*Actinobacillus*] *rossii* (H. Christensen et al., unpublished observation). Two taxa, [*P.*] *trehalosi* and [*P.*] *betyae* were without close phylogenetic relationship to other taxa of Pasteurellaceae. Additionally, 16S rRNA sequences are available for all four serovars (T3, T4, T10 and T15) of [*P.*] *trehalosi* showing a high similarity of 98.6–99.7%. [*Pasteurella*] *testudinis* finally forms an out-group, together with the unnamed taxon 14 of Bisgaard (Dewhirst et al., 1993; Olsen et al., 2003; Fig. 1). In conclusion, the genus *Pasteurella* is polyphyletic with members included within four out of the thirteen monophyletic groups, just as *Pasteurella* have two out of ten single taxa not belonging to groups of Pasteurellaceae (see Table 1).

Taxonomy

The taxonomic description includes classification and nomenclature. For the phenotypic characters, refer to Tables 2, 3, 4 and 5.

The current classification and nomenclature of *Pasteurella* has been based mainly on phenotypic characterization and DNA-DNA hybridization. *Pasteurella* is separated from other genera within Pasteurellaceae by the lack of β -hemolysis and the ability of acid formation from (–)-D-fructose, (+)-D-galactose, (+)-D-mannose and sucrose, and lack of acid formation from glycosides and (+)-D-melibiose. A positive test is also obtained with porphyrin and phosphatase (Table 2). According to DNA-DNA hybridization, *Pasteurella* sensu stricto presently contains species interrelated at or above a DNA binding level of 55% (Mutters et al., 1989). Analysis by crossed immunoelectrophoresis and polyamines have confirmed the phylogenetic separation of *Pasteurella* sensu stricto into the core group including the type species, the avian group, in addition to *P. langaa* and *P. anatis* (Schmid et al., 1991; Busse et al., 1997).

The Core Group of *Pasteurella* sensu stricto

Pasteurella multocida has been isolated from both normal and diseased mammals and birds. *Pasteurella multocida* is the type species of the genus and can be separated from other members of *Pasteurella* mainly by positive reactions for ornithine decarboxylase, indole and acid formation from (–)-D-mannitol, and lack of acid production from maltose and dextrin. *Pasteurella multocida* was subdivided into three subspecies, *P. multocida* subsp. *multocida*, *P. multocida* subsp. *gallicida* and *P. multocida* subsp. *septica*, on the basis of differences in acid production from dulcitol and (–)-D-sorbitol (Mutters et al.,

1985a; Table 3). High phenotypic variability has been reported for *P. multocida* including phenotypes for which classification into the existing subspecies categories has not been possible (Biberstein et al., 1991; Fegan et al., 1995; Petersen et al., 1998; see also Identification and Typing). V-factor requiring strains also may occur (Krause et al., 1987). DNA-DNA-binding values of 84–100, 91–100 and 89–100% were found within the three subspecies (*multocida*, *gallicida* and *septica*, respectively), but binding values as low as 55% between the subspecies were also reported (Mutters et al., 1985a). The closest related taxon was *P. dagmatis* with a DNA-DNA-binding value of 62% (Mutters et al., 1985a). A 16S rRNA sequence variation of 1.4–2% was found between *P. multocida* subsp. *septica* and *P. multocida* subsp. *multocida* and subsp. *gallicida*, while subsp. *multocida* and subsp. *gallicida* were nearly identical (Boerlin et al., 2000; Petersen et al., 2001a). Partial *atpD* DNA sequence comparison also showed that the subspecies of *P. multocida* differed, and confirmed 16S rRNA results indicating *P. multocida* subsp. *septica* diverged mostly from the other two subspecies (Petersen et al., 2001a). *Pasteurella canis* has mainly been isolated from dogs. *Pasteurella canis* is urease negative and ornithine decarboxylase positive. Acid is not produced from (+)-L-arabinose, dulcitol, (–)-D-sorbitol or maltose. *Pasteurella canis* is separated from *P. multocida* by the lack of acid production from (–)-D-mannitol. Biotype 1 of *P. canis* exhibits a positive reaction for indole, while biotype 2 strains are indole negative (Mutters et al., 1985a). DNA-DNA relatedness among *P. canis* strains was 80%, while the closest relative of *P. canis* was *P. avium* with a DNA-DNA binding value of 69% (Mutters et al., 1985a). Biovar 2 shares genotypical similarity with *P. multocida*, and *P. canis* should be reclassified only to include the characteristics of biovar 1 (Christensen et al., 2002a). *Pasteurella stomatis* has mainly been obtained from dogs and cats. *Pasteurella stomatis* is indole positive, but urease-negative. No acid is produced from (+)-L-arabinose, (+)-D-xylose, dulcitol, (–)-D-mannitol, (–)-D-sorbitol or maltose. *Pasteurella stomatis* is ornithine decarboxylase negative compared to *P. multocida* and *P. canis*, both being positive. DNA-DNA relatedness among *P. stomatis* strains was 91% and the closest relative to *P. stomatis* was *P. avium* with a DNA-DNA binding value of 81% (Mutters et al., 1985a). *Pasteurella dagmatis* has mainly been isolated from dogs and cats. *Pasteurella dagmatis* is positive for indole and urease and produces acid from (+)-D-maltose, while acid is not produced from (+)-L-arabinose, (+)-D-xylose, dulcitol, (–)-D-mannitol or (–)-D-sorbitol. Small amounts of gas may occur from (+)-D-glucose.

Table 1. Species and species-like taxa of *Pasteurella* with indication of type strain, phylogenetic group, genome size and G+C content.

Table 2. Common phenotypic characters of species classified with *Pasteurella sensu stricto*.^a

Positive characters ^b	Tween 20
Hugh-Leifson medium, glucose fermentation	Tween 80
Porphyrin test	Pigment
Nitrate, reduction	<i>meso</i> -Erythriol
Alanine aminopeptidase	(-)-D-Adonitol
Phosphatase, alkaline	(-)-L-Xylose
(-)-D-Ribose	(+)-D-Fucose
(-)-D-Fructose	(+)-D-Glucose, gas ^d
(+)-D-Galactose	(+)-L-Rhamnose
(+)-D-Glucose, acid	(-)-L-Sorbose
(+)-D-Mannose	Cellobiose
Sucrose	β -Glucosidase (NPG)
Negative characters ^c	(+)-D-Melibiose
Gram stain	(+)-D-Melizitose
Motility, 22 and 37°C	(+)-D-Glycogen
β -Hemolysis (bovine blood)	Inulin
Citrate, Simmons	Esculin
Mucate, acid	Amygdalin
Malonate, base	Arbutin
H ₂ S/TSI	Gentiobiose
KCN, growth	Salicin
Methyl red, 37°C	(+)-D-Turanose
Voges-Proskauer, 37°C	β -N-CH ₃ -glucosamide
Nitrate, gas	α -Fucosidase (ONPF)
Arginine dehydrolase	α -Galactosidase
Lysine decarboxylase	β -Glucuronidase (PGUA)
Phenylalanine deaminase	α -Mannosidase
Gelatinase	β -Xylosidase (ONPX)

Abbreviations: TSI, triple sugar iron; NPG, *p*-nitrophenyl- β -D-glucopyranoside; ONPF, *o*-nitrophenyl-D-fucopyranoside; PGUA, 4-nitrophenyl-D-glucopyranosiduronic acid; and ONPX, *o*-nitrophenyl- β -D-xylopyranoside.

^aIncludes the 16S rRNA cluster 12 (*P. multocida*, *P. dagmatis*, *P. canis*, *P. stomatis*, and *Pasteurella* species B), cluster 18 (*P. gallinarum*, *P. avium*, *P. volantium*, *Pasteurella* species A, and *P. anatis*), and *P. langaa* according to Olsen et al. (2003).

^bCharacters are positive for 90% or more of strains of each species.

^cCharacters are negative for 90% or more of strains within each species analyzed.

^dWeak positive reactions observed with *P. dagmatis*.

Table 5. Colonial and morphological characters of *Pasteurella*.

Species/taxon	Colonial characteristics on blood agar or chocolate agar	Deviation from coccoid and short rod cell morphology
<i>Pasteurella multocida</i>	Colonies smooth, mucoid or rough on bovine or sheep blood or chocolate agar with light grayish color, and diameter 1–2mm Indole-producing strains have a distinct odor	Pleomorphic rods and short filaments can be seen in broth media and older cultures. Many strains produce capsules
<i>P. dagmatis</i>	Smooth and grayish white, diameter 1–1.5mm	ND
<i>P. canis</i>	Small colonies, diameter 0.5–1.5mm	ND
<i>P. stomatis</i>	Small colonies, diameter 0.5–1.5mm	Bipolarly stained ends in the Gram stain
<i>P. gallinarum</i>	Similar to <i>P. multocida</i>	Bipolar staining occurs
<i>P. avium</i> biovar 1	Colonies on chocolate agar usually smooth, convex, slightly yellowish or grayish-white	Coccoid to pleomorphic rods, singly or in short chains
<i>P. volantium</i>	Similar to <i>P. avium</i> biovar 1, but more yellow	Cells coccoid, singly or in short chains
<i>P. anatis</i>	Circular, smooth, grayish-white, diameter 1.5–2mm	ND
<i>P. langaa</i>	Circular, smooth, grayish-white, diameter 1–1.5mm	ND
<i>Pasteurella</i> species B	Colonies are similar to <i>P. canis</i> or <i>P. stomatis</i>	ND
[<i>P.</i>] <i>mairii</i>	Colonies on sheep blood agar are round, grayish, semi-transparent, diameter 1–2mm, and have narrow zone of hemolysis	Cells are small bacilli or coccobacilli
[<i>P.</i>] <i>bettyae</i>	Colonies on sheep blood agar are round, grayish, semi-transparent, and have diameter 1–2mm	Cells are small <1µm
[<i>P.</i>] <i>caballi</i>	Smooth, grayish/yellowish on blood agar, and have diameter 1.0–1.5mm	Cells are rod-shaped 0.8–1.0 × 1.3–1.9µm, bipolarly stained, singly or in pairs, and occasionally curved filamentous forms
[<i>P.</i>] <i>testudinis</i>	Hemolytic zone on sheep blood agar, and diameter 0.5–1.0mm	Cells pleomorphic rods, 0.2 × 1.5–2.0µm, and capsule-like surface
[<i>P.</i>] <i>trehalosi</i>	On sheep blood agar, round, grayish, semi-transparent, diameter 1–2mm, and pronounced zone of hemolysis	ND

Abbreviation: ND, no deviation.

From Sneath and Stevens (1990) and Mutters et al. (2003).

Positive reactions in urease, maltose and dextrin separate the species from *P. multocida*, *P. canis* and *P. stomatis*, all of which are negative in these characters. The DNA-binding value was 84%

within the species, and the species with the highest level of DNA-DNA relatedness was *P. gallinarum* with 78% (Mutters et al., 1985a). *Pasteurella* species B seems to be associated mainly

with cats and dogs. *Pasteurella* species B is ornithine decarboxylase positive, and acid is produced from (+)-D-xylose, dulcitol and maltose. Acid is not produced from (+)-L-arabinose, (–)-D-mannitol, or (–)-D-sorbitol. Urease is not produced. The species with the highest level of DNA-DNA relatedness to *Pasteurella* species B was *P. stomatis* and *P. canis* with 60% (Mutters et al., 1985a).

The Avian Group of *Pasteurella* sensu stricto

Pasteurella gallinarum, *P. volantium*, *P. avium* and *Pasteurella* species A are phylogenetically related (Dewhirst et al., 1993) and referred to as the Avian group of *Pasteurella* (Olsen et al., 2003) because they have been isolated mainly from birds. All taxa are indole negative compared to the “core-group” of *Pasteurella*, which are positive. In addition, the species *P. volantium*, *P. avium* and *Pasteurella* species A are V-factor dependent. The existence of nicotinamide adenine dinucleotide (NAD)-independent strains (Bragg et al., 1997) still remains to be confirmed genetically. *Pasteurella gallinarum* has been isolated from different lesions of fowl. *Pasteurella gallinarum* is urease and ornithine decarboxylase negative and produces acid from maltose and trehalose, whereas acid is not formed from (+)-L-arabinose, dulcitol, (–)-D-mannitol and (–)-D-sorbitol. High genome relatedness was exhibited between *Pasteurella gallinarum* strains (90% DNA-DNA binding) and the closest relative was *P. dagmatis* with 78% DNA-DNA binding (Mutters et al., 1985a). *Pasteurella volantium* has been obtained mainly from domestic fowl. *Pasteurella volantium* produces acid from (–)-D-mannitol, maltose and dextrin and is separated from *P. gallinarum* by the (–)-D-mannitol fermentation and V-factor requirement. The species produces yellowish colonies on chocolate agar. DNA-DNA relatedness among *P. volantium* strains was 81% and the species with the highest level of DNA-DNA relatedness was *P. gallinarum* with 72% (Mutters et al., 1985a). *Pasteurella avium* has been isolated mainly from the wattles of domestic fowl. *Pasteurella avium* is ornithine decarboxylase and indole negative, and acid is not formed from (+)-L-arabinose, dulcitol, (–)-D-mannitol, (–)-D-sorbitol, maltose, dextrin or raffinose. A negative reaction in (–)-D-mannitol, maltose and dextrin separates *P. avium* from *P. volantium*, which are positive. Biotype 1 strains of *P. avium* require V-factor, while biotype 2 strains do not. The DNA-DNA relatedness among *P. avium* strains was 88%, while the species with the highest level of DNA-DNA relatedness was *P. stomatis* with 81% (Mutters et al., 1985a). Biotype 2 strains

isolated from calves (Mutters et al., 1985b) share genotypical similarity with *P. multocida*, and reclassification with this species has been proposed (Christensen et al., 2002a). *Pasteurella* species A has been isolated from the infraorbital sinuses of chickens. The ornithine decarboxylase test is negative, and acid is not formed from (–)-D-sorbitol. *Pasteurella* species A is positive in (+)-L-arabinose compared to the other species of *Pasteurella*, which are negative. DNA-DNA relatedness was 83% among *Pasteurella* species A strains, and the species with the highest level of DNA-DNA relatedness was *P. gallinarum* with 63% (Mutters et al., 1985a).

Pasteurella anatis and *P. langaa* differ from the other eleven taxa of *Pasteurella* sensu stricto in many characters (Tables 3 and 4) in accordance with their distinct phylogenetic positions. *Pasteurella anatis* has been isolated from the intestinal and respiratory tract of ducks, but bovine isolates also have been isolated. *Pasteurella anatis* is urease, ornithine decarboxylase and indole negative, and acid is produced from (+)-D-xylose and (–)-D-mannitol. The lowest level of DNA-DNA relatedness among *P. anatis* strains was 94%, and the species with the highest level of DNA-DNA relatedness was *P. multocida* with 51% (Mutters et al., 1985a). Reclassification of *P. anatis* to *Gallibacterium anatis* has subsequently been proposed on the basis of phylogenetic, geno- and phenotypic characteristics (Christensen et al., 2003a). *Pasteurella langaa* has been isolated from the respiratory tracts of chickens. *Pasteurella langaa* is mostly negative for catalase, while ornithine decarboxylase, indole and *p*-nitrophenyl-β-D-galactopyranoside (PNPG) reactions are negative. Acid is produced from (–)-D-mannitol. The species with the highest level of DNA-DNA relatedness was *P. volantium* with 57% (Mutters et al., 1985a).

Taxa Excluded from *Pasteurella* sensu stricto

On the basis of DNA-DNA hybridizations, seven species were excluded from *Pasteurella* sensu stricto: [*P.*] *pneumotropica*, [*P.*] *aerogenes*, [*P.*] *mairii*, [*P.*] *caballi*, [*P.*] *bettyae*, [*P.*] *trehalosi* and [*P.*] *testudinis* (Mutters et al., 1989; Mutters et al., 2003).

[*Pasteurella*] *pneumotropica* has been isolated from rodents. The species is pheno- and genotypically diverse and only the biovar Jawetz, including the type strain, will be described further. Phenotypic characters separating the [*P.*] *pneumotropica*-complex and related taxa have previously been reported by Mutters et al. (1989). Although meeting the general characters of *Pasteurella*, it becomes obvious from the studies of Ryll et al. (1991) and Nicklas et al. (1993)

that the taxonomy of rodent Pasteurellaceae presently is unclear and should be subjected to major changes as indicated by 16S rRNA sequencing (Fig. 1) and on the basis of DNA-DNA hybridization (Ryll et al., 1991). The DNA-DNA relatedness among [*P.*] *pneumotropica* (Jawetz biovar) strains was 46–95%, and the closest relatives of [*P.*] *pneumotropica* (Jawetz biovar) were found to be [*Actinobacillus*] *muris* with 42% and taxon 3 of Bisgaard with 36% (Piechulla et al., 1985; Ryll et al., 1991).

[*Pasteurella*] *aerogenes* (type strain) was originally isolated from pigs. Subsequent investigations, however, seem to indicate a broader host spectrum (Bisgaard, 1993), just as genetic investigations have demonstrated the need of a revised description of this species (see Phylogeny). The species with the highest level of DNA-DNA relatedness to [*P.*] *aerogenes* was [*P.*] *pneumotropica*, but this was only 25% (Mutters et al., 1985a). So far [*P.*] *mairii* has only been isolated from pigs. It is urease positive and indole negative, and it was sensitive to malachite green and 1% Teepol (Sneath and Stevens, 1990). DNA-DNA hybridization between [*P.*] *mairii* and the type strain [*P.*] *aerogenes* showed only 47% relatedness (W. Mannheim, unpublished). [*Pasteurella*] *aerogenes* differs from *Pasteurella* in phosphatase and gas production from glucose, while [*P.*] *mairii* can be separated from *Pasteurella* on the basis of 4-nitrophenyl- β -D-glucopyranoside (NPG), 4-nitrophenyl- β -D-glucopyranosiduronic acid (PGUA) and o-nitrophenyl- β -D-xylopyranoside (ONPX) assays (Magne Bisgaard, unpublished results). [*Pasteurella*] *bettyae* isolated from humans differs from *Pasteurella* in catalase, gas production from glucose, and the inability to produce acid from (-)-D-galactose and sucrose. [*Pasteurella*] *bettyae* and [*P.*] *pneumotropica* (its closest relative) share 29% DNA-DNA relatedness (Mutters et al., 1985a).

[*Pasteurella*] *caballi* has so far only been isolated from horses and from infected horse bite wounds and is separated from *Pasteurella* by its aerogenic capacity and negative catalase reaction. The closest phylogenetic relative of [*P.*] *caballi* is *P. langaa* with 53% DNA-DNA binding (Schlater et al., 1989; Fig. 1). [*Pasteurella*] *trehalosi* is associated mainly with a well-defined systemic disease of young adult sheep. [*Pasteurella*] *trehalosi* has been excluded from *Pasteurella* by hemolysis, weak pigment formation, production of acid from glycosides, and lack of acid formation from (+)-D-galactose, in addition to genotypical differences (Mutters et al., 1985a; DeLey et al., 1990; Dewhirst et al., 1993). A strain of [*P.*] *trehalosi* and the type strain of *Mannheimia haemolytica* shared only 18%

DNA-DNA relatedness; however, the DNA-DNA relatedness values between a strain of [*P.*] *trehalosi* and the type strain of [*P.*] *testudinis* was 62% (Mutters et al., 1985a). [*Pasteurella*] *testudinis*, which seems to be associated with desert tortoises, differs from *Pasteurella* in hemolysis and production of acid from (+)-L-rhamnose, (+)-D-melibiose and glycosides, while no acid is produced from (+)-D-mannose (Snipes and Biberstein, 1982; M. Bisgaard, unpublished results). DNA-DNA relatedness values between the type strain and another representative of [*P.*] *testudinis* was 95%. The species with the highest level of DNA-DNA relatedness was [*P.*] *trehalosi* with 62% (Mutters et al., 1986a).

Recently, taxa of *Pasteurella* have been reclassified with other genera: *P. ureae* was reclassified as *Actinobacillus ureae* (Mutters et al., 1986b), the *P. haemolytica*-complex (including *P. granulomatis*) was reclassified with the new genus *Mannheimia* (Angen et al., 1999), and *Pasteurella lymphangitidis* was excluded from the family (Mutters et al., 1985a). A new species, *P. skyensis*, was recently proposed by Birkbeck et al. (2002); however, this species is probably not a member of Pasteurellaceae because it lacks nitrate reduction capability and 16S rRNA similarity with other members of the family. These taxa will not be described further.

Colonial Characteristics

Surface colonies of members of the genus *Pasteurella* on bovine blood agar or chocolate agar are circular, slightly raised and regular with an entire margin. The surface of the colonies is normally smooth, shiny and nontransparent with a grayish tinge. A diameter of 0.5–2.0 mm is normally observed after 24 hours of aerobic incubation at 37°C. After further incubation, the size of the colonies might reach a diameter of up to 3 mm (Table 5); however, a significant variation in colonial morphology is observed even within the same species. β -Hemolysis on bovine or ovine blood agar is not seen, but a greenish discoloration may occur. Occasionally, yellowish colonies can be seen especially with strains of *P. dagmatis*, *P. canis* and *P. volantium*. Isolates of *P. multocida* from the respiratory tract of ruminants, pigs and rabbits may form large, watery, mucoid colonies, which may collapse after 48 hours of incubation. Rough colonies of *P. multocida* are formed from filamentous noncapsulated cells (Rimler and Rhoades, 1989). Growth in broth usually causes turbidity, but granular growth may occur (Mutters et al., 2003). Colony morphology of the species excluded from *Pasteurella* does not differ significantly from the general description (Table 5).

Cellular Morphology

Cells of *Pasteurella* appear as coccobacilli or rods, generally 0.3–1.0 µm in diameter and 1.0–2.0 µm in length. Cells occur singly, in pairs, or less frequently in short chains depending on the growth stage. Pleomorphism occurs in older cultures. The bacteria are Gram negative. Bipolar staining can be observed with Giemsa or Wright's stain, especially in tissues. The bacteria are not acid-fast, do not form endospores, and are nonmotile (Table 5).

Fimbriae

Pili have been observed with *P. multocida*. Pili were only expressed at higher growth temperatures and are probably involved in adherence to host mucosal cells (Rebers et al., 1988; Isaacson and Trigo, 1995).

Cell Wall

Polyamine analysis has shown that members of the genus *Pasteurella* possess 1,3-diaminopropane, putrescine, cadaverine, spermidine and spermine in the cell wall. The triamine, symnorspermidine, was found only in the core-group of *Pasteurella sensu stricto* (*P. multocida*, *P. canis*, *P. dagmatis*, *P. stomatis* and *Pasteurella* sp. B; Busse et al., 1997). Further characteristics of true members of the genus *Pasteurella* are high amounts of quinones with the chain length of eight (ubiquinone, menaquinone and demethylmenaquinone; Mutters et al., 1993).

Capsule

Virulent strains of *P. multocida* usually produce capsules, and the capsular antigens are intimately associated with lipopolysaccharide (LPS; Rimler and Rhoades, 1989). The capsule of *P. multocida* is composed of polyanionic polysaccharides resulting in strong hydrophilic properties (Rimler and Rhoades, 1989; Boyce et al., 2000b). It has further been observed that encapsulated strains are more resistant to phagocytosis and to complement and much more virulent in mice compared to nonencapsulated strains (Boyce et al., 2000b). Hyaluronic acid has been found in capsular material of capsular type A of *P. multocida*, and the biosynthesis pathway has been described (DeAngelis, 1999; Boyce et al., 2000b). The capsular material of serogroup B strains contains monosaccharides, arabinose, mannose and galactose, and serogroup B strains have been found to produce hyaluronidase (Rimler and Rhoades, 1989). The chemical composition of the other capsular types is less

known. The capsular material of isolates belonging to capsular group D showed similarities with hyaluronic acid; however, it was not susceptible to hyaluronidase but was susceptible to heparinase III and chondroitinase AC (Boyce et al., 2000b). The capsular material of serogroup F strains was susceptible to chondroitinase AC, but not to hyaluronidase or heparinase III (Boyce et al., 2000b). The antigenic properties of capsular polysaccharides are used for typing of *P. multocida* (see Identification and Typing).

Outer Membrane Proteins

This group of molecules includes components of importance for virulence, e.g., a 37.5-kDa porin of *P. multocida* affecting bovine neutrophils (Galdiero et al., 1998). Outer membrane proteins (OMPs) also include molecules with specific antigenic properties, such as LPS interacting with the host immune system. Diversity was observed between OMP profiles of [*P.*] *trehalosi* and *M. haemolytica* (Davies and Quire, 1996). A relationship between *P. multocida*, *P. gallinarum*, [*Haemophilus*] *paragallinarum*, *P. volantium* and *P. avium* was inferred through the binding of a polyclonal antibody raised against a putative porin of *P. multocida* (Lubke et al., 1994; Hartmann et al., 1996). Monoclonal antibodies raised against different OMPs of *P. multocida* allowed the detection of strains of capsular type D of *P. multocida* or of the species *P. stomatis*, *P. gallinarum*, *P. betti*, *Pasteurella* sp. B and *P. canis*, but not other Gram-negative bacteria (Marandi and Mittal, 1995; Marandi and Mittal, 1996). A purified OMP of 87 kDa could be identified in all serotypes of *P. multocida* by Western-blot analysis (Ruffolo and Adler, 1996). The expression of OMPs by *P. multocida* was influenced by iron (Choi-Kim et al., 1991; Zhao et al., 1995; Ruffolo et al., 1998), and crossreaction between antibodies from pigs and fowl with iron-regulated OMPs of *P. multocida* isolated from pigs and fowl was further found (Zhao et al., 1995). In [*P.*] *testudinis*, iron-regulated OMPs were also identified (Snipes et al., 1995), and in vivo propagation led to the expression of additional OMPs (Choi et al., 1989).

Lipid Polysaccharides

Lipopolysaccharides (LPS) of *P. multocida* consist of lipid A, which is responsible for the endotoxic activity, an oligosaccharide core, and the O-antigenic unit consisting of repeating carbohydrate units. The chemical composition of the oligosaccharide and the O-antigenic unit is 2-keto-3-deoxyoctonate, L-glycero-D-mannose, heptose, glucose and glucosamine. In some

cases galactose, rhamnose, D-glycero-D-mannoheptose, glucosamine, glucosamine-6-phosphate, and galactosamine have been found (Rimler et al., 1984; Rimler and Rhoades, 1989; Conrad et al., 1996). The LPS is believed to form the basis of specificity for the somatic typing system (Rimler and Rhoades, 1989). Capsulation did not affect the LPS profile (Rimler, 1990).

Antigens

Studies of *Pasteurella* antigens (including LPS, OMP and the toxin protein of *P. multocida*) have been reviewed by Confer (1993). On the basis of average linkage cluster analysis of precipitate values obtained by crossed immunoelectrophoresis a close antigenic relationship between species of the genus *Pasteurella* was found (Schmid et al., 1991).

Fatty Acids

The fatty acids, C_{14:0}, C_{16:1}, C_{16:0}, 3-OH-C_{14:0}, C_{18:2}, C_{18:1} and C_{18:0}, were found in human strains of *P. multocida* subsp. *multocida*, *P. multocida* subsp. *septica*, *P. canis*, *P. stomatis*, *P. dagmatis* and *P. caballi* (Schlater et al., 1989; Holst et al., 1992). The fatty acid profiles of the species of the family Pasteurellaceae were found to be indistinguishable (Schlater et al., 1989; Holst et al., 1992; Mutters et al., 1993). Subsequently the growth medium was found to affect the fatty acid profiles (Boot et al., 1999).

Other Factors

Serogroups A, B, D and E have been found to produce neuraminidase, which is cell-associated and involved in virulence, although the mechanism has not been determined precisely (Rimler and Rhoades, 1989).

Habitat

Detailed investigations on the habitat of the different species of *Pasteurella* using phenotypic, as well as genotypic, methods for identification remain to be performed. For the same reason, our present knowledge on location and carrier rates remains uncertain. A habitat outside animals also remains to be demonstrated.

On the basis of previous reviews and subsequent updates, the habitat of *P. multocida* seems very varied compared to other Pasteurellaceae (Bisgaard et al., 1994); however, many publications do not allow separation at subspecies level, but since *P. multocida* subsp. *multocida* is most frequently reported, a very broad host

spectrum for this subspecies is anticipated. *Pasteurella multocida* subsp. *gallicida* has most frequently been isolated from birds, and occasionally from pigs (Bowles et al., 2000; Muhairwa et al., 2000). *Pasteurella multocida* subsp. *septica* has been isolated more frequently from cats than dogs (Dziva et al., 2001; Muhairwa et al., 2001b), and infrequently from humans (Boerlin et al., 2000).

Pasteurella dagmatis, *P. canis* biovar 1 and *Pasteurella* species B are mainly associated with the oral and nasal mucosa of cats and dogs and have been isolated from human wound infections resulting from bites inflicted by these animals (Bisgaard, 1993; Frederiksen, 1993). [*Pasteurella*] *bettyae* has been isolated from human Bartholin's gland abscesses and a finger infection. In addition, it has been implicated in genital infections, but is only rarely invasive (Frederiksen, 1993). *Pasteurella avium* has been isolated from domesticated and wild birds (biovar 1) and from the lungs of calves suffering from pneumonia (biovar 2). *Pasteurella volantium* also seems to be bird-associated (Bisgaard, 1993), although a single strain has been isolated from human tongue (Kilian, 1976). Strains of *P. gallinarum* are normally associated with different pathological lesions of poultry (including chronic fowl cholera in chickens; Bisgaard, 1993), but isolation from guinea fowls (Mohan et al., 2000) and pigs (Blackall et al., 2000b) has also been reported. Isolates from other hosts probably represent misidentification (Christensen et al., 2002b). *Pasteurella* species A has been reported from both domesticated and wild birds (Bisgaard, 1993). *Pasteurella anatis* has been isolated from the intestinal and respiratory tracts of ducks and geese. Bovine strains seem to be isolated less frequently (Christensen et al., 2003a). *Pasteurella langaa* has been found in the respiratory tracts of apparently healthy chickens. [*Pasteurella*] *aerogenes* and [*P.*] *mairii* seem to be associated with pigs, which may result in disease conditions including abortions and septicemia in piglets. Several cases of pig or boar bite infections have been reported (Lester et al., 1993) just as [*P.*] *aerogenes* has been isolated from a human case of abortion (Thorsen et al., 1994). [*Pasteurella*] *caballi* has been isolated from respiratory and genital tract infections in horses, from wound infections in humans, and from humans who have had contact with horses, including wound infection after horse bites (Schlater et al., 1989; Bisgaard et al., 1991a; Escande et al., 1997). [*Pasteurella*] *testudinis* has been isolated from Californian desert tortoises (*Gopherus agassizii*; Snipes and Biberstein, 1982). [*Pasteurella*] *trehalosi* is an important pathogen for young adult sheep, where it causes a well-defined systemic

disease (Gilmour and Gilmour, 1989). [*Pasteurella*] *trehalosi* is also commonly associated with healthy lambs and ewes (Al-sultan and Aitken, 1985; Gilmour and Gilmour, 1989). In addition, [*P.*] *trehalosi* has been reported from cattle and pigs (Fodor et al., 1999).

Isolation

Collection of Sample Material

Sterile cotton swabs are generally recommended for collection of suspect sample material under as sterile conditions as possible. These are streaked onto blood agar plates or other enriched isolation media such as brain heart infusion broth. Blood from cattle with suspected hemorrhagic septicemia that is swabbed from the heart or other affected tissues within a few hours after death can be used for isolation. If the carcass has undergone considerable decomposition, the bone marrow may be examined. In pigs and other animals with atrophic rhinitis, the affected nasoturbinalia are swabbed, and the swabs are streaked onto blood agar plates or incubated further in brain heart infusion broth (Amigot et al., 1998). Chickens suspected of being carriers of *P. multocida* are sampled from the cloaca or upper respiratory mucosal surfaces (Lee et al., 2000).

Enrichment and Isolation Procedures

For standard isolations, bovine or sheep blood or chocolate agar may be used. By tradition, the V-factor-requiring species are isolated on media supplemented with 5% serum or blood and crossinoculated with a *Staphylococcus* or an *Acinetobacter* strain to provide the V-factor (Mutters et al., 2003). *Pasteurella multocida* can be obtained from contaminated material by subcutaneous or intraperitoneal inoculation of mice with subsequent isolation from the spleen (Carter and De Alwis, 1989; Muhairwa et al., 2001a). Several selective media have been developed for isolation of *P. multocida* (Rimler and Rhoades, 1989; Moore et al., 1994; Lee et al., 2000), just as transport media have been investigated (Kawamoto et al., 1997).

Identification and Typing

The first step for identification of the *Pasteurella* is to select single colonies suspected to represent members of Pasteurellaceae and to make a broth subculture for replating, thereby ensuring a pure culture. Then the properties of the culture (Gram negative, nonmotile, oxidase and catalase positive, nonhemolytic, phosphatase positive, breaks

down glucose fermentatively without gas formation in Hugh and Leifson's medium, and does not grow in the presence of 4.5% NaCl) are confirmed. Characters stated in Table 2 can be used for separation of *Pasteurella* from other genera of the family Pasteurellaceae in combination with characters used for separation of taxa of *Pasteurella* (Tables 3 and 4). The use of host range (Table 6) should be considered to improve the diagnostic level. Inclusion of reference strains for control of media and tests is highly recommended.

For the separation of *Pasteurella* from other genera of Pasteurellaceae, it is important to make a distinction between the indole positive species (*P. multocida*, *P. canis*, *P. stomatis*, *P. dagmatis* and *Pasteurella* sp. B primarily associated with mammals) and indole negative species (the avian-associated species, *P. gallinarum*, *P. volantium*, *Pasteurella* sp. A, *P. avium*, *P. anatis* and *P. langaa*). Members of *Pasteurella* sensu stricto never exhibit hemolysis on ordinary media. The only *Pasteurella* species exhibiting gas production is *P. dagmatis*. With the exception of *P. dagmatis*, all species of *Pasteurella* are urease-negative, while members of *Actinobacillus* are positive. Acid formation has not been found in (+)-L-rhamnose, and *m*-inositol fermentation is only observed with some *P. gallinarum* isolates. *Pasteurella* produce acid from (–)-D-fructose, (+)-D-mannose and (+)-D-galactose in contrast to many *Haemophilus* and *Actinobacillus* species. Differences in (+)-D-mannose utilization and indole production separate the genera *Mannheimia* and *Pasteurella* (Mutters et al., 2003) (Table 2).

As stated previously, extended characterization and the inclusion of reference strains are highly needed to allow correct identification at the species level (see also Taxonomy). The differential characteristics of species of *Pasteurella* are given in Table 3. Maltose fermentation, in certain cases, may not be a reliable character for identification of *P. multocida* because maltose-positive strains of this species have been reported (Petersen et al., 1998). Identification of *P. gallinarum* from other sources than birds (Bisgaard and Mutters, 1986; Boot and Bisgaard, 1995) and, in rare cases pigs, should be questioned and further identification performed by 16S rRNA sequencing (Christensen et al., 2002b). Full sequencing of 16S rRNA genes and cooperation with reference laboratories are recommended in doubtful cases.

Commercial test systems are of little value in the identification of *Pasteurella* to the species level (Inzana et al., 2000). Polymerase chain reaction (PCR) presently represents the most promising tool for semiautomated identification (see below; Christensen et al., 2003b). PCR tech-

Table 6. Hosts and diseases of *Pasteurella*.

niques should be preferred when isolates are nonpathogenic to mice (Townsend et al., 2000).

PCR Tests

PCR tests have been developed for specific detection of *P. multocida* (see Christensen et al., 2003b). *Pasteurella multocida* can be detected at the species level by a PCR targeting the *rrl* gene (Mifflin and Blackall, 2001) or by targeting of an unknown gene (Townsend et al., 1998). Species-specific detection may also be used to target the *psl* gene coding for the P6-like protein, but this test needs verification by hybridization (Kasten et al., 1997). Isolates of *P. avium* biovar 2 and *P. canis* biovar 2 also are detected by *P. multocida*-specific PCR (Townsend et al., 1998; Mifflin and Blackall, 2001); however, this is probably related to misclassification because *P. avium* biovar 2, *P.*

canis biovar 2, and *P. multocida* share 16S rRNA gene sequences (Dewhirst et al., 1993; Christensen et al., 2002a). A PCR test specific at the biovar level has also been reported for [*P.*] *pneumotropica* (Kodjo et al., 1999b). Bacterial reference and type strains for use as positive controls are listed in Table 1. Positive control strains are of importance for verification of DNA extracted from swabs and to document the performance of the PCR. Negative controls without DNA are included to detect contaminating DNA.

PCR might be performed with DNA extracted directly from swabs or from bacteria isolated on plates. Both strategies allow pre- and post-mortem identification. For fast identification and to limit overgrowth by other bacteria, PCR performed directly on DNA extracted from swabs is preferred. Swabs are soaked in phosphate-

buffered saline, the cell debris spun down and the supernatant centrifuged to collect a pellet containing the bacteria, which is treated with proteinase K (see Chen et al., 1996). For subsequent processing, reference is made to the specific tests.

In Situ Hybridization

An in situ hybridization test for *P. multocida* based on the recognition of a specific part of the 16S rRNA sequence has been described, and the presence of *P. multocida* verified in sections of infected chicken and pig lungs (Mbuthia et al., 2001). The test was recommended for verification of pure cultures of *P. multocida* on smears as well as for histopathological detection of *P. multocida* within infected tissues. Similar to the PCR tests described for *P. multocida*, the in situ hybridization test also detects biovar 2 strains of *P. avium* and *P. canis*, which are routinely misclassified and should be reclassified with *P. multocida* (Christensen et al., 2002a).

Typing Methods

Typing methods are used for detailed characterization to investigate the diversity of taxa of *Pasteurella* and for the study of pathogenesis and epidemiology. If the discriminatory power of these methods is sufficient, they can be used to collect data about certain members of the bacterial population and their relation to disease and hosts.

Biotyping

Major differences in phenotypical characters have been reported for *P. multocida* (Tables 3 and 4) and have been utilized for biotyping (Heddlestone, 1976; Biberstein et al., 1991; Bisgaard et al., 1991b; Fegan et al., 1995). *Pasteurella canis* and *P. avium* are also separated in two biovars (Mutters et al., 1985b; Mutters et al., 1985a). On the basis of differences in reactions for β -glucosidase and production of acid from glycosides (esculin, amygdalin and gentiobiose), three biotypes have been reported for [*P.*] *trehalosi* (M. Bisgaard, 2002, unpublished observation). Biotyping also has been used within the former [*P.*] *haemolytica* complex in ruminants and avian species, within [*P.*] *aerogenes* and taxon 2 and 3 of Bisgaard (Bisgaard, 1993). Biotyping of *P. multocida* has previously been discussed by Christensen and Bisgaard (Christensen and Bisgaard, 1997; Christensen and Bisgaard, 2000). Biotyping seems most relevant for taxonomic investigations.

Serotyping

CAPSULAR SEROTYPING The capsular typing system reported by Carter (1955) is based upon passive hemagglutination of erythrocytes sensitized by capsule antigen. Five capsule types (A, B, D, E and F) are distinguished (Rimler and Rhoades, 1987; Rimler and Rhoades, 1989). Isolates causing hemorrhagic septicemia belong to serogroups B or E, and isolates causing fowl cholerae to serogroup A. Isolates causing atrophic rhinitis usually belong to serogroup D (Boyce et al., 2000b). So far, capsular typing by the passive hemagglutination test has only been performed in a few laboratories around the world, and presumptive identification of capsular types A, D and F by capsule depolymerizations with mucopolysaccharidases has been reported (Rimler, 1994). Subsequent cloning and sequencing of the entire capsular biosynthetic loci of *P. multocida* strains X-73 (A : 1; Chung et al., 1998) and M 1404 (B : 2; Boyce et al. 2000a) and nucleotide sequence analysis of the biosynthetic region from each of the remaining three capsule types D, E and F identified capsule-specific regions and allowed development of a highly specific multiplex capsular PCR assay (Townsend et al., 2001), which is now used as an alternative to the passive hemagglutination assay. Recently problems with the separation of capsular types A and F in the test have been reported (Townsend et al., 2002). The reference strains for the *P. multocida* capsular types should be requested from national veterinary reference laboratories (e.g., The Royal Veterinary College, London; The National Animal Disease Center, Ames, Iowa, United States) or strain collections like American Type Culture Collection (ATCC), Culture Collection, University of Göteborg, Dept. of Clinical Bacteriology, Göteborg, Sweden (CCUG) and National Collection of Type Cultures, Central Public Health Laboratory, London, United Kingdom (NCTC).

SOMATIC SEROTYPING Sixteen serotypes (1 through 16) were recognized by somatic antigen typing on the basis of the gel diffusion precipitin tests of Heddlestone et al. (1972). Somatic serotyping has also been done by tube agglutination (Namioka, 1978), but this method is not widely used, as judged by references in the literature. Serological typing of *P. multocida* has been reviewed and discussed by Rimler and Rhoades (1989). Comparative studies by Brogden and Packer (1979) indicated that a serotype determined by the capsular typing system did not correlate with somatic serotyping. Four serovars, T3, T4, T10 and T15, have been described for [*P.*] *trehalosi* (Biberstein, 1978; Fraser et al., 1982). High homogeneity of LPS profiles was found

within [*P.*] *trehalosi*. Four OMP profiles were found in [*P.*] *trehalosi*, but only one was serotype specific. Serotypes T4 and T15 were suggested to be highly related on the basis of OMP and LPS profiling (Davies and Quirie, 1996).

Typing of Virulent Members of *Pasteurella*

HEMORRHAGIC SEPTICEMIA Specific detection of genotypes with the potential of causing hemorrhagic septicemia belonging to serotype B:2 was possible by a PCR targeting the 16S to 23S rRNA spacer (Brickell et al., 1998), and serotypes B:2, B:5 and B:2,5 with another PCR test (Townsend et al., 1998). In rare cases, serotype D could also be detected (Townsend et al., 2002). Using the PCR protocol for isolates of *P. multocida* causing hemorrhagic septicemia, good correlation to an enzyme-linked immunosorbent assay (ELISA) was found (Brickell et al., 1998). *Pasteurella multocida* strain ATCC 6530 might be used as a positive control with this test.

FOWL CHOLERA Tools for typing and identification of virulent strains of *P. multocida* associated with fowl cholera remain to be developed.

PORCINE ATROPHIC RHINITIS Serological detection of toxinogenic *P. multocida* is possible using an ELISA (DAKO PMT ELISA) based upon monoclonal antibodies raised against the toxin (Foged et al., 1988). Virulent genotypes of *P. multocida* causing porcine atrophic rhinitis might also be identified by PCR, and in several tests, the gene *tox*A (coding for the toxin) has been used as the target (Nagai et al., 1994; Kamp et al., 1996; Lichtensteiger et al., 1996; Hotzel et al., 1997). (See also Christensen et al. [2003b] for a comparison of these PCR tests.) Good correspondence has been reported between detection by PCR and by in vitro and in vivo detection methods of the toxic protein of *P. multocida* (Nagai et al., 1994; Jong et al., 1996; Kamp et al., 1996; Lichtensteiger et al., 1996). *Pasteurella multocida* strain NCTC 12178 might be used as a positive control for *tox*A-positive isolates.

LEUKOTOXIN Green et al. (1999) were able to differentiate between cytotoxic and noncytotoxic [*P.*] *trehalosi* strains using PCR for the coding region of *lkt*A (leukotoxin). The PCR method of Fisher et al. (1999) yielded bands of the expected size in selected strains of *P. trehalosi*, *Mannheimia haemolytica*, *M. glucosida*, *M. granulomatis* and *M. varigena* (Fisher et al., 1999; J. Larsen, unpublished observation), which shows that the detection of the *lkt* gene is not allowing species-specific detection of [*P.*] *trehalosi*, since this gene is also found in *Mannheimia* spp. (Fisher et al., 1999; Green et al., 1999).

MULTILOCUS ENZYME ELECTROPHORESIS Multilocus enzyme electrophoresis (MLEE) was used by Blackall et al. (Blackall et al., 1998; Blackall et al., 1999) to investigate the population structure of *P. multocida* and for the epidemiological study of fowl cholera in turkeys.

DNA-BASED TYPING METHODS These methods are required for epidemiological investigations because biotyping and serotyping methods do not have enough discriminatory power to trace outbreak-clones of *Pasteurella*. Individual serotypes might include virulent as well as avirulent isolates.

RESTRICTION ENDONUCLEASE ANALYSIS Restriction endonuclease analysis (REA) typing with *Sma*I-*Sal*I digestion was used by Snipes et al. (1989) to study the transmission of isolates of *P. multocida* from wild animals to turkeys. REA typing with *Bgl*II digestion was later used to separate vaccine strains of *P. multocida* from outbreak strains (Kim and Nagaraja, 1990). REA typing based upon *Hha*I digestion was evaluated for separating wildtype vaccine strains and serotypes of *P. multocida*, and it was concluded to be useful for accurate identification and epidemiologic studies (Wilson et al., 1993). REA typing using *Hpa*II for digestion of DNA was used for epidemiological studies of porcine pasteurellosis and fowl cholera caused by *P. multocida* (Christensen et al., 1998; Blackall et al., 2000b; Muhairwa et al., 2000). REA typing is useful for fast separation of small numbers of very closely related isolates, and for the same reasons *Hpa*II digestion has been used most widely, recently.

RANDOM AMPLIFIED POLYMORPHIC DNA Random amplified polymorphic DNA (RAPD) was used for genotypic separation of isolates of *P. multocida* obtained from various animal sources in Zimbabwe. Poor relationship between RAPD-genotype, host and disease was obtained. Porcine isolates tended to cluster together as did cattle isolates from hemorrhagic septicemia (Dziva et al., 2001). Repetitive extragenetic palindromic (REP)-PCR fingerprinting was of great value for epidemiological typing of *P. multocida* to separate isolates from different outbreaks (Gunawardana et al., 2000; Amonsin et al. (2002)) identified certain turkey associated clones by the technique. REP-PCR was used for epidemiological investigation of human isolate of *Pasteurella multocida* and was also found valuable for identification to the subspecies level (Chen et al., 2002). Enterobacterial repetitive intergenic consensus (ERIC)-PCR was not sufficiently discriminatory for epidemiological study of *P. multocida* isolated from dogs (Loubinoux et al., 1999). RAPD represents the method of

choice for fast screening of many isolates among which high genotypic resolution is not obvious.

RIBOTYPING Ribotyping based upon *EcoRI* digestion was used by Snipes et al. (1989) for fingerprinting of *P. multocida* isolated from turkeys and wildlife, while ribotyping using *HindIII* digestion later was concluded to be useful for epidemiological studies of toxin-producing *P. multocida* (Fussing et al., 1999). Petersen et al. (1998) used ribotyping for identification of phenotypic variant strains of *P. multocida*. Ribotyping with *HpaII* digestion was used to study porcine pasteurellosis and fowl cholera caused by *P. multocida* (Christensen et al., 1998; Blackall et al., 2000b; Bowles et al., 2000; Muhairwa et al., 2000). *HpaII* digestion showed slightly higher resolution than *HindIII* digestion in the study of Petersen et al. (1998), but almost the same number of ribotypes in the study of Bowles et al. (2000). When highly diverse collections of *P. multocida* were studied with respect to origin and phenotype by ribotyping using *HpaII* digestion of DNA, high diversity was observed with many clusters and without correlation between these clusters and subspecies of *P. multocida* (Blackall et al., 1998; Petersen et al., 2001a). Consequently, ribotyping based upon *HpaII* digestion is too sensitive for identification at the subspecies level of *P. multocida* and is best suited for epidemiological investigation of strains with only minor genotypical differences.

PULSED FIELD GEL ELECTROPHORESIS Pulsed field gel electrophoresis (PFGE) also represents a reliable method for tracing closely related isolates of *Pasteurella*. For macrorestriction digestion, *NotI*, *SaII* and *SmaI* have been used (Blackwood et al., 1996; Kodjo et al., 1999a; Boerlin et al., 2000). PFGE was of great value for epidemiological typing of *P. multocida*, separating isolates from different outbreaks (Gunawardana et al., 2000). Characterization of [*P.*] *trehalosi* resulted in 26 PFGE profiles compared to 20 ribotypes and 15 RAPD types (Kodjo et al., 1999a). PFGE was used to investigate the transmission of *P. multocida* from pet animals to babies suffering from meningitis (Blackwood et al., 1996; Boerlin et al., 2000).

The ability of five DNA-based typing methods (REA, ribotyping, PFGE, REP-PCR and MLEE) to type a set of *P. multocida* isolates was compared by Blackall and Mifflin (2000a). The five methods showed various relationships between the outbreak strains, but the between-method agreement was strong.

AMPLIFIED FRAGMENT LENGTH POLYMORPHISM
Amplified Fragment Length Polymorphism

(AFLP) was used for molecular epidemiologic analysis of avian isolates of *Pasteurella multocida* involved in fowl cholera (Amonsin et al., 2002).

In conclusion, identification and typing will be dominated by molecular-based techniques. For the present, PCR-based tests for species identification and PCR-based "serotyping," and REA and PFGE for the study of highly related isolates seem most valuable.

Preservation

Survival of *Pasteurella* outside their host and in artificial media seems limited. Survival for about a week is possible on enriched media like blood or chocolate agar stored at room temperature, or better at 4°C in a plastic jar or plastic bag to avoid desiccation. Freezing at -80°C is recommended for longer storage. Cultures will remain viable for years when frozen at -80°C in liquid media such as proteose peptone broth containing 20% glucose or glycerol. For long-term survival, either lyophilization or storage in liquid nitrogen is recommended. Both techniques preclude selection of mutants that occur during repeated subculturing. Survival at -80°C for more than two decades has been observed with suspension cultures in calf serum with 7.5% glucose (Lapage and Redway, 1974) in our laboratory.

Physiology

Members of *Pasteurella* are aerobic to microaerophilic or are facultatively anaerobic. Increased carbon dioxide may improve the growth of surface cultures of certain isolates. They are chemoorganotrophic with both oxidative and fermentative types of metabolism. The major route for carbohydrate utilization is the pentose phosphate pathway, whereas the citric acid cycle only operates supplementarily (Rimmler and Rhoades, 1989). The electron transport system is cytochrome-based with oxygen, nitrate or fumarate as the terminal electron receptor. Nitrate reductase is produced. Most species are V-factor (NAD requirement for growth) and X-factor (requirement for hemin or other porphyrins) independent, but V-factor-requiring strains do occur. So far, V-factor requirement has been reported for *P. avium*, *P. volantium* and *Pasteurella* sp. A (Mutters et al., 1985b) and some isolates of *P. multocida* subsp. *multocida* (Krause et al., 1987). Cysteine, nicotinamide, pantothenate and thiamine are required for growth of *P. multocida* (Rimmler and Rhoades, 1989). Growth can be observed in a wide mesophilic range (25–42°C). *Pasteurella multocida*, *P. stomatis*, *P. dagmatis* and *P. gallinarum* have optimal growth

optimum at 36°C. With *P. multocida*, the optimal growth temperature for avian strains might be as high as 42°C, compared to 36°C for mammalian strains.

Genetics

Genome Structure

The mol% G+C of the DNA of *Pasteurella* is 37.7–45.9. Most species excluded from *Pasteurella* sensu stricto all fall within this range also, but [*P.*] *testudinis* has a slightly higher value with a G+C content of around 47 mol% (Table 1). The genome molecular weights are $1.4\text{--}2.1 \times 10^9$ Da (Table 1).

The genomic sequence has been determined for an avian strain of *P. multocida* (Pm70) isolated from a fowl cholera-infected chicken and found to be 2,257,487 bp long (1.5×10^9 Da), with 2,014 predicted coding regions (May et al., 2001). The variation between DNA sequences of 16S rRNA and *atpD* and *infB* genes of the type strain and strain Pm 70 of *P. multocida* is 1–2% (H. Christensen, unpublished observation). A similar level of genetic divergence has been observed between the subspecies of *P. multocida* (Petersen et al., 2001a) and shows that the genome-sequenced strain Pm 70 is genetically divergent from the type strain of *P. multocida*. Similar but not identical genomic structure of strains of *P. multocida* was found by I-CeuI restriction analysis; however, a few bovine strains diverged (Liu et al., 1999). Strains of *P. multocida* have been found to possess six ribosomal operons (Liu et al., 1999; May et al., 2001). Few coding genes have been characterized in *Pasteurella* and exclusively in *P. multocida*. The putative genes for catabolic pathways of asparagine, histidine, leucine, lysine, and phenylalanine were absent in the *P. multocida* genome (May et al., 2001).

Gene expression of *P. multocida* was studied by microarray analysis in relation to nutrient limitation (Paustian et al., 2002). About one third of the presumed genes of the organism changed expression level when nutrient regimes were changed. In rich media, genes involved in energy metabolism, protein-, nucleotide- and lipid synthesis, iron transport and cellular binding were upregulated, whereas genes encoding for amino acid biosynthesis, protein transport, OMP and heat shock proteins were upregulated in nutrient-deficient media (Paustian et al., 2002).

Description of Virulence Genes

The formation and activity of the dermonecrotic toxin found in some representatives of capsular types A and D of *P. multocida* associated with

atrophic rhinitis in pigs has been described (Hunt et al., 2000). The toxin is acting by inducing increased levels of DNA synthesis in the host cells by stimulating intracellular signalling cascades (Rozengurt et al., 1990; Lax and Grigoriadis, 2001). The C terminus was found to possess catalytic activity and the N terminus to facilitate cell binding (Busch et al., 2001; Pullinger et al., 2001). The protein toxin is coded by *toxA* as shown by cloning and characterization (Lax and Chanter, 1990; Petersen and Foged, 1990b).

Genes of the repeat-in-toxin (RTX) family have only been found in [*P.*] *aerogenes* and [*P.*] *mairii*, but not in all strains of these species and not in the type strains of these species (Kuhnert et al., 1997). The leukotoxin and its structural gene, *lktA*, has been found in all serotypes of [*P.*] *trehalosi* (Shewen and Wilkie, 1982; Burrows et al., 1993; Davies et al., 2001) and the sequence of *lktCABD* characterized in detail (Davies et al., 2001; Davies et al., 2002). Similar to other members of the RTX gene family, *lktA* encodes the protoxin, *lktC* is responsible for posttranscriptional activation, and *lktB* and *lktD* for transport of the toxin. Leukotoxin has been shown to play a major role in pathogenesis (Petras et al., 1995; Highlander et al., 2000) and was responsible for the β -hemolytic phenotype on blood agar (Murphy et al., 1995; Fedorova and Highlander, 1997). A correlation between PCR-positive isolates for the *lkt*-gene and β -hemolytic activity was found by Fisher et al. (1999), and isolates with β -hemolytic activity had a greater potential to cause disease (Jaworski et al., 1998). Lateral DNA transfer and recombination have been important evolutionary mechanisms in diversification of the *lkt* gene (Davies et al., 2001; Davies et al., 2002).

Except for the *toxA* gene, no genes directly involved in virulence have been found in *P. multocida* by the newest molecular screening techniques, and other virulence factors of *P. multocida* are incompletely understood. In vivo expression technology (IVET) showed in vivo expression in mice of lipoproteins, enzymes involved in pyrimidine synthesis, general biosynthetic and metabolic functions, in addition to proteins with unknown functions (Hunt et al., 2001). Microarray analysis of *P. multocida* showed two gene regions homologous to the filamentous hemagglutinin gene of *Bordetella pertussis*, coding for proteins important in host cell binding and immunity (May et al., 2001). By signature-tagged mutagenesis in a mouse model, genes assumed to be directly involved in virulence were identified homologous to those involved in hemolysin synthesis, hemagglutinin synthesis, *Ton*-dependent transport of iron,

adherence, and capsular synthesis, in addition to genes involved in amino acid and nucleotide biosynthesis (Fuller et al., 2000).

Common to these investigations of gene expression are the activation of iron uptake systems. Iron uptake systems are indirectly related to virulence, since the iron concentration is limited in the host and iron is essential for the function of metabolic electron transport chains of the pathogen. Microarray analysis of *P. multocida* under iron-restricted conditions showed increased expression of the gene homologs *yfeABCD*, *fbpABC*, *fecBCD*, *tonB* and *exbBD* involved in iron uptake (Paustian et al., 2001) and further studies with different iron source suggested that different pathway might respond to inorganic and organic source of iron in *P. multocida*. A 95 kDa-OMP protein was extracted from *P. multocida* under iron-depleted conditions, which showed identity to the heme acquisition system receptor for *P. multocida*. Cloning and sequencing of the gene had 98% similarity with the *HasR* homolog of *P. multocida* Pm 70 and a predicted molecular weight of 96 kDa (Prado et al., 2002).

Fimbria and Capsule

Capsulation and piliation are potential virulence factors and their genes have been characterized (Boyce et al., 2000b; Doughty et al., 2000). The biosynthetic locus of serogroups A and B have been characterized in detail. Both consist of three parts, two involved in capsule translocation and phospholipid substitution and one in formation of activated sugar monomers and assembly of the polysaccharide polymers. The biosynthetic locus of serogroup A consists of 11 open reading frames (ORFs), nine for which functions have been proposed: four genes (*hexABCD*) are involved in export of polysaccharides, and the next five genes (*hyaABCDE*) encode proteins involved in the formation of activated sugar monomers and the assembly of hyaluronic acid. Finally two genes (*phyAB*) are involved in phospholipid substitution of hyaluronic acid before translocation. Fifteen ORFs have been proposed for the capsule biosynthetic locus of serogroup B, seven for which functions have been proposed: the first four (*cexABCB*) are probably involved in export of the polysaccharide, the fifth and the last genes (*lipA* and *lipB*) are suggested to be involved in phospholipid substitution, and nine genes (*hcbABCDEFGHI*) are proposed to be involved in formation and assembly of activated sugar monomers (Boyce et al., 2000a; Boyce et al., 2000b).

The genes of type 4 fimbriae have been characterized in serovars of *P. multocida* (Ruffolo et al., 1997; Doughty et al., 2000).

Plasmids and Transposons

Plasmids of sizes between 1.3 and 100 kbp have been found in *P. multocida* (Hunt et al., 2000), whereas plasmids between 1.8 and 28 kbp have been observed in *[P.] aerogenes* (Kehrenberg and Schwarz, 2001a). Plasmids have been found related to resistance to streptomycin, sulfonamides, tetracycline, penicillins, kanamycin and chloramphenicol (Rimler and Rhoades, 1989; Hunt et al., 2000). The distribution of identical nonconjugative R plasmids of *P. multocida* did not follow the clonal population structure (Ikeda and Hirsh, 1990). The transposon *Tn5706* is the only transposable element identified in *P. multocida* (Hunt et al., 2000).

Antibiotic Resistance

Genes encoding for resistance to antibiotics have been associated with small plasmids, or with conjugative or nonconjugative transposons (Kehrenberg et al., 2001b). Most of the plasmids associated with resistance are less than 10 kbp (Kehrenberg et al., 2001b). Most antibiotic resistance genes are thought to have been transferred to *Pasteurella* from Enterobacteriaceae or other bacteria, but *tet(H)* has only been found in *Pasteurella* (Kehrenberg et al., 2001b).

Pasteurella multocida has been found to carry *tet(H)* and *tet(M)* genes with both plasmid and chromosomal locations (Hansen et al., 1993; Hansen et al., 1996; Chaslus-Dancla et al., 1995; Kehrenberg and Schwarz, 2001a). The tetracycline-resistance genes *tetR* and *tet(H)* were found located in the plasmid-borne *Tn5706* (Kehrenberg et al., 1998). *[Pasteurella] aerogenes* carried *tet(B)* or *tet(H)* genes encoding resistance to tetracycline. The *tet(B)* gene was located on *Tn10* and chromosomally integrated. However, a plasmid-location was also reported (Kehrenberg and Schwarz, 2001a; Kehrenberg et al., 2001b).

Genes encoding β -lactams were located on small plasmids of 4.1–4.4 kb in *P. multocida*, while genes encoding aminoglycoside resistance were mainly associated with small plasmids of less than 10 kb in *P. multocida* (Kehrenberg et al., 2001b). A human strain produced ROB-1 β -lactamase encoded from a plasmid location (Rosenau et al., 1991). Chloramphenicol resistance was encoded by the resistance genes *catAI* and *catAIII* detected on plasmids of *P. multocida* and *[P.] aerogenes* (Vassort-Bruneau et al., 1996; Kehrenberg et al., 2001b).

Population Genetics

The population structure of *P. multocida* and *[P.] trehalosi* has been concluded to be clonal as

determined by MLEE, with genetic diversity of between 0.289 and 0.474 (Davies et al., 1997; Blackall et al., 1998; May et al., 2001). Genotypical characterization of diverse collections of isolates of *P. multocida* and *P. gallinarum* with respect to hosts, diseases and geographic origin has indirectly confirmed the clonal population structure (Dziva et al., 2001; Petersen et al., 2001a; Muhairwa et al., 2001b; Christensen et al., 2002b).

Antibiotic resistance has probably evolved by horizontal spread of genes both within *Pasteurella* and between *Pasteurella* and other bacterial groups (Kehrenberg and Schwartz, 2000). A plasmid with resistance to tetracycline could be found in both *P. multocida* and [*P.*] *aerogenes* (Kehrenberg and Schwartz, 2000).

Ecology

The natural reservoir of *Pasteurella* seems to be the mucosal membranes of the respiratory, genital and intestinal tract of mammals and birds (Table 6). Most members of *Pasteurella* are regarded as opportunistic pathogens that may colonize and form part of the indigenous flora of the mucous membranes of the respiratory, genital and intestinal tracts of vertebrates; however, certain virulent strains of *P. multocida* might occur as obligate parasites. The fact that *Ascaridia galli* infections (followed by secondary *P. multocida* infection) resulted in more birds with pathological lesions and continued *P. multocida* excretion (Dahl et al., 2002) suggests interactions between *Pasteurella* and members of the indigenous flora of the different mucosal membranes remain to be elucidated (in addition to interactions between *Pasteurella* and the host).

The strongly hydrophilic capsule of *P. multocida* probably aids in the protection of the bacteria against dehydration, improving transmission from host to host and survival in the environment (Rimler and Rhoades, 1989; Boyce et al., 2000b). It has further been observed that encapsulated strains are more resistant to phagocytosis and to complement and are much more virulent in mice compared to nonencapsulated strains (Boyce et al., 2000b).

Pasteurella multocida has been isolated worldwide among terrestrial, as well as aquatic, species of mammals and birds. Investigations on the carrier rate of *P. multocida* in healthy commercial poultry flocks and fowl cholera-affected flocks showed that the latter carried *P. multocida* at a significantly higher prevalence in the mucosa of the cloaca than in the pharynx, while the opposite was observed in birds from healthy flocks. A different clone was found in each of four outbreaks of fowl cholera on a farm during a

two-year surveillance period, indicating that extra-animal survival seems limited (Muhairwa et al., 2000). *Pasteurella canis* biovar 1, *P. stomatitis*, *P. dagmatis* and *Pasteurella* sp. B are mainly associated with the oral and nasal mucosa of dogs and cats (Bisgaard, 1993; Ganiere et al., 1993; Muhairwa et al., 2001a). *Pasteurella gallinarum* is normally reported in association with different pathological lesions in poultry (Bisgaard, 1993), rarely in pigs, and isolations from rodents and humans probably represent misidentification (Christensen et al., 2002b). A single isolate has been reported from a normal duck (Muhairwa et al., 2001a). *Pasteurella avium*, *P. volantium*, *Pasteurella* sp. A, *P. langaa* and *P. anatis* are all associated with birds. [*Pasteurella*] *trehalosi* seems to be associated with the mucosal surfaces of the upper respiratory tract of ruminants (Gilmour and Gilmour, 1989). A range of characteristics can be correlated with the parasitic lifestyle of these organisms including requirements for growth factors, low oxygen tolerance, mechanisms for iron competition, surface structures to endure the host immune system, and tendencies for host association between certain taxa and orders of vertebrates, mostly domesticated. *Pasteurella multocida* represents an exception associated with a wide range of hosts; however, the possibility that certain clones are associated with diseases of a particular animal species remains to be investigated.

Epidemiology

The distribution of members of *Pasteurella* in clinically diseased-, subclinically affected-, and healthy animal populations has been investigated during the last decade by molecular comparisons at the DNA level. The use of molecular methods has tremendously improved tracing of bacterial isolates, especially for taxa like *P. multocida*, which have a broad host reservoir resulting in many potential possibilities for transmission.

Studies based on genotypical analysis have shown a global distribution of taxa investigated (e.g., Fussing et al., 1999; Christensen et al., 2002b; F. Dziwa et al., manuscript submitted). The impact of animal transportation and trade on the distribution pattern is, however, difficult to evaluate.

Spread of Members of *Pasteurella* Between Animals

In an early molecular study by ribotyping of fowl cholera in turkeys, the outbreak was found to be caused by multiple ribotypes (Snipes et al., 1989). This result seems to be atypical since later

studies have shown that outbreaks most often have been clonal. Blackall et al. (1999) conducted REA, ribotyping and MLEE studies of fowl cholera outbreaks in turkeys and concluded outbreaks were often caused by only a single clone, and different clones were involved in different outbreaks. This conclusion was confirmed by Muhairwa et al. (2000), who found only single clones of *P. multocida* were involved in duck cholera outbreaks as shown by REA and ribotyping; however, some clones were found in more flocks. In respect to porcine isolates, the situation was almost similar when isolates collected from different farms were investigated. Few ribotypes could be isolated from different farms with mostly only a single type isolated on a farm (Bowles et al., 2000). This distribution was explained by movement of pigs between farms. In a more detailed study of porcine pasteurellosis caused by *P. multocida* involving only four outbreaks, a single clone was found responsible for two outbreaks, while two or three types were associated with the other two outbreaks. The presence of two or more types on farms was proposed to be related to the transfer of animals between farms (Blackall et al., 2000b); however, the significance of management remains to be investigated further. Healthy dogs most frequently were colonized by a single REA-type of *P. multocida*, and REA types were probably exchanged between dogs by contact (Loubinoux et al., 1999). The same was found for *[P.] trehalosi* where outbreaks were found to be caused by specific clones, as documented by REA-typing and ribotyping. Furthermore, the transmission from ewes to lambs of specific strains was shown (Jaworski et al., 1998).

Transmission of *P. multocida* between wild animals and turkeys was studied systematically by Snipes et al. (1988). *Pasteurella multocida* was isolated from a range of wild animals, and inoculation of turkeys with these isolates also showed differences in virulence. A tendency was demonstrated towards a higher virulence of isolates from wild animals close to turkey farms (Snipes et al., 1988). In a further study it was confirmed that some of the isolates from wildlife shared REA-types with outbreak strains from turkeys (Snipes et al., 1989). The observation that 80% of the outbreaks in poultry in Denmark included flocks that had been in contact with the avifauna, and the fact that a highly virulent clone of *P. multocida* subsp. *multocida* involved in two outbreaks of fowl cholera in wild birds in Denmark in 1996 was subsequently re-isolated from a domestic duck cholera outbreak, confirm that the avifauna represent a risk for industrial production (Christensen et al., 1998; Christensen et al., 1999). The importance of wild birds as a reservoir for fowl cholera was subsequently underlined by experimental studies (Petersen et al., 2001b).

In an extensive study in Tanzania, *P. multocida* was isolated from 0.7% of chickens, 7% of ducks, 4% of dogs and 51% of cats investigated. Although the poultry was scavenging and in contact with dogs and cats, it was not possible to isolate bacteria with identical genotypes (as determined by REA and ribotyping) from poultry, dogs and cats (Muhairwa et al., 2001a, b). It was concluded that most of the colonization of animals, including colonization resulting in disease, was by a single isolate (DNA type); however, the potential for spread of *P. multocida* between different animal groups including the spread of virulent strains, requires further study.

Spread of Members of *Pasteurella* Between Animals and Man

There are indications that *P. multocida* is more frequent in chronic respiratory tract disease of farmers than in that of other groups, probably reflecting cross-infection from domestic animals (Frederiksen, 1989). Similar observations have been made in relation to the isolation of *[P.] aerogenes* from a human abortus and pig bite wounds (Lester et al., 1993; Thorsen et al., 1994).

Isolates of *P. multocida* associated with meningitis in babies have been traced to pet animals by PFGE. In one case, a human isolate of *P. multocida* subsp. *septica* shared a PFGE profile with an isolate obtained from the house cat (Boerlin et al., 2000). In another case, identity was not found, but *P. multocida* could be isolated both from pets and family members (Blackwood et al., 1996). These studies have documented that isolates of *P. multocida* might be transferred from domestic animals, including healthy pets, resulting in serious diseases in man.

Diseases and Treatment

Pasteurella multocida causes a wide range of diseases in animals. Capsule type A, serotypes 1, 3 and 4, are recognized as the primary cause of fowl cholera in poultry and wild birds (Rhodes and Rimler, 1989; Christensen and Bisgaard, 1997; Table 6). Disease may appear as an acute septicemia characterized by disseminated intravascular coagulation, petechial or ecchymotic hemorrhages, multifocal necroses and fibrinous pneumonia. Chronic infections may involve a variety of types and local infections (Christensen and Bisgaard, 1997; Christensen and Bisgaard, 2000).

Pasteurella multocida serotypes B : 2 and E : 2 are associated with hemorrhagic septicemia of cattle, water buffaloes, and occasionally other species, resulting in major economic losses, mainly in Southeast Asia (Carter and Alwis, 1989; de Alwis, 1995). Respiratory diseases in

cattle, including bronchopneumonia in feedlot cattle and enzootic pneumonia of calves less than 6 months old, are mainly associated with capsule type A (Frank, 1989). Outbreaks of septicemia in fallow deer have also been reported (Eriksen et al., 1999). Infections of major economic importance in pigs include atrophic rhinitis and bronchopneumonia (Chanter and Rutter, 1989; Gardner et al., 1994; Nagai et al., 1994). These syndromes are caused by capsular types A and D. Members of *P. multocida* belonging to capsule types A and D may also cause pneumonia in pigs (Chanter and Rutter, 1989). Severe cases of atrophic rhinitis are mainly associated capsule type D. Pulmonary lesions may result in blood-borne dissemination to the kidneys in pigs (Buttenschøn and Rosendal, 1990). Recently, *P. multocida* was proposed to be associated with porcine dermatitis and nephropathy syndrome (PDNS; Lainson et al., 2002).

Atrophic rhinitis caused by *P. multocida* has also been reported in goats and rabbits (Baalsrud, 1987; DiGiacomo et al., 1989). In addition to major diseases in production animals, *P. multocida* is recovered from a wide range of sporadic infections in many other species, including laboratory animals (Manning et al., 1989), dogs and cats (Mohan et al., 1997) and other mammals (DiGiacomo et al., 1989).

Pasteurella multocida and other species of the 16S rRNA cluster 12 are considered as zoonotic pathogens (Bisgaard et al., 1994). Most human infections associated with *Pasteurella* species result from animal bites. The species usually observed in these infections are *P. multocida* subsp. *multocida* and subsp. *septica*, *P. canis*, *P. dagmatis* and *P. stomatis* (Holst et al., 1992; Escande and Lion, 1993; Matsui et al., 1996). Other infections in humans associated with *P. multocida* include necrotizing fasciitis (Hama-moto et al., 1995), chronic lung abscess (Machiels et al., 1995), endocarditis (Genne et al., 1996), meningitis (Boocook and Bowley, 1995; Armstrong et al., 2000), pulmonary diseases (Ory et al., 1998), peritonitis (Wallet et al., 2000), septicemia (Greif et al., 1986), periocular abscess and cellulitis (Hutcheson and Magbalon, 1999), and granulomatous hepatitis (Chateil et al., 1998).

Pasteurella gallinarum was originally associated with enzootic, chronic fowl cholera in chickens (Hall et al., 1955). In addition, *P. gallinarum* has been reported from acute fowl cholera (Yadav et al., 1977). Other lesions include conjunctivitis, sinusitis, tracheitis, airsacculitis, hepatitis, abscess formation, endocarditis, salpingitis, oophoritis, peritonitis and synovitis (Christensen et al., 2002b). The reasons for differences in virulence between strains of *P. gallinarum* remain to be investigated (Shivaprasad and Droual, 2002).

[*Pasteurella*] *trehalosi* is mainly associated with sheep in which they may cause acute sys-

temic pasteurellosis. The pathogenesis remains unclear since pneumonia in specific-pathogen-free (SPF) lambs has not been reported with [*P.*] *trehalosi*. In addition, all serovars have been associated with disease conditions (Gilmour and Gilmour, 1989). The disease potential of strains classified with the [*P.*] *aerogenes*-complex remains to be investigated in more detail (Bisgaard, 1993). Recent investigations (Kuhnert et al., 2000) showed that a new RTX operon, named *paxCABD* could be detected specifically in clinical isolates of [*P.*] *aerogenes*, which were all associated with abortion in pigs. Mice infected by [*P.*] *pneumotropica* developed bronchopneumonia, lobar pneumonia, or pleuropneumonia (Macy et al., 2000).

The mechanisms behind virulence and pathogenesis of fowl cholera remain unclear (Christensen and Bisgaard, 1997; Christensen and Bisgaard, 2000). Cloning of the toxin gene from toxigenic *P. multocida* into *Escherichia coli* has enabled a more detailed description of the pathogenesis of atrophic rhinitis (Kamps et al., 1990; Lax and Chanter, 1990; Petersen and Foged, 1990b). The toxin associated with atrophic rhinitis in pigs and other animals is encoded by the *toxA* gene (Petersen, 1990a). Sequencing of the entire genome of a common avian clone of *P. multocida* (May et al., 2001) has provided a basis for future research into virulence factors and mechanisms of pathogenesis including host specificity of certain disease aspects of this pathogen. Some virulence factors have been identified.

Purified LPS of *P. multocida* was found to cause suppurative airsacculitis, pleuritis and pneumonia in turkeys (Kunkle and Rimler, 1998). In addition, LPSs of *P. multocida* capsular type A were found to affect the humoral and cell-mediated immune response (Maslog et al., 1999).

Antibiotic Sensitivity

Minimum inhibitory concentrations (MICs) of selected antimicrobial agents have been reviewed by Rimler and Rhoades (1989). Most human isolates of *Pasteurella* are susceptible to penicillin (Holst et al., 1992), the antibiotic of choice for local wound infections (Bisgaard et al., 1994). Other β -lactam antibiotics should be effective as well (Jorgensen et al., 1991). Macrolides and, especially for urinary and respiratory infections, fluoroquinolones, appear to be useful in human and animal infections (Gaillot et al., 1995; Hanan et al., 2000). [*Pasteurella*] *caballi* and [*P.*] *testudinis* have been found susceptible to ampicillin (Snipes and Biberstein, 1982; Schlater et al., 1989). Most strains are also susceptible to tetracyclines, but [*P.*] *testudinis* is resistant (Holst et al., 1992; Snipes and Biber-

stein, 1982). Marbofloxacin, a fluoroquinolone exclusively for veterinary use, might be useful in treatment of dogs and cats (Spreng et al., 1995). Tilcomycin, a macrolide antibiotic for use in veterinary medicine, proved to be effective in the treatment of pasteurellosis in rabbits (McKay et

al., 1996). Recent publications recommended treatment of animal infections with sulfonamides, tetracyclines, streptomycin and florfenicol (Kehrenberg et al., 2001b; Table 7). Laboratory mice might be treated for *[P.] pneumotropica* with enrofloxacin (Macy et al., 2000).

For feed medication of turkeys, chlortetracycline, furazolidone, penicillin, and neomycin-oxytetracycline might be used, while sulfadimethoxine, penicillin and tetracycline might be used for medication in water (Morris et al., 1989).

Applications

Vaccines for prevention of diseases have only been developed for a few members of *Pasteurella* so far. Either live attenuated bacteria or bacterins have been used for vaccination (Confer, 1993). With live attenuated vaccines, immunity might be obtained against different serotypes. These vaccines, however, might revert to the virulent wild type or just become pathogenic under conditions such as stress or by immunosuppression (Morris et al., 1989).

Classical live vaccine strains include CU and M-9 strains against fowl cholera (e.g., Kim and Nagaraja, 1990). An interest in improving and developing more defined strains of *P. multocida* for use as live attenuated vaccines, however, is strongly needed (Boyce et al., 2000b). An *aroA* mutant strain, PMP3, of *P. multocida* was protective against homo- and heterologous challenge in a mouse model (Homchampa et al., 1997). Two *aroA* mutant strains, PMP1 and PMP3, were further tested in a chicken model where protection was achieved by intratracheal vaccination and challenge (Scott et al., 1999). Examples of live *P. multocida* vaccines of avian origin are Avichol, Orachol, PM one vax, M Nine Vax, M Nine Vax C (Schering-Plough Animal Health, USA), Choleravac-PM-1 (Intervet, USA) and ViClemcol-C (Vineland Laboratories, USA). The vaccine, Once PMH (Intervet), includes both modified avirulent *P. multocida* and *Mannheimia haemolytica*.

The alternative to live vaccines is to use killed bacteria or cellular components (bacterins). This approach excludes a disease risk through reversion to the virulent form, but these vaccines are normally only active against homologous serotypes and the vaccine normally has to be injected. A purified OMP of *P. multocida* was able to protect mice against homologous challenge with *P. multocida* (Ruffolo and Adler, 1996). In addition, it was found that OMPs expressed under iron-limiting conditions improved protection against heterologous challenge in mice compared to those expressed under normal iron concentrations (Ruffolo et al., 1998). Examples of bacterins of *P. multocida* are Inacti VACFC3 (Maine Biological Laboratories, USA) and PABAC (Fort Dodge Animal Health, USA). Presponse HM (Fort Dodge Laboratories) is a bacterin based

upon both *P. multocida* and *Mannheimia haemolytica*.

The Genus *Cardiobacterium*

SYDNEY M. HARVEY AND JAMES R. GREENWOOD

The genus *Cardiobacterium* consists of one species, *Cardiobacterium hominis*, originally designated “group II D organisms” until further described and named by Slotnick and Dougherty (1964). This organism is a fastidious, facultatively anaerobic, nonmotile, pleomorphic Gram-negative rod with a fermentative type of metabolism.

The first known report of these organisms was by Tucker et al. (1962). This paper described four cases of endocarditis caused by a *Pasteurella*-like organism. These isolates and two subsequent isolates, also from cases of endocarditis, were designated as “group II D” by the Centers for Disease Control, Atlanta, GA, until the name *C. hominis* was proposed by Slotnick and Daugherty (1964). The current assumption is that infectious endocarditis is the only disease caused by *C. hominis* in humans. This assumption may be valid or it may be based on a lack of more complete knowledge of the biology of the organism. Although past isolation of *C. hominis* has been almost exclusively limited to blood cultures, there have been at least two isolations from cerebral spinal fluid (Slotnick, 1968; Francioli et al., 1983).

Reference is not an exact match Slotnick (1964, 1968), in an attempt to extend our knowledge of the human occurrence of this organism, used fluorescent antibody smears and culture techniques to sample other sites. He and his colleagues isolated *C. hominis* from nose and throat specimens of 68 of 100 persons sampled, from cervical and vaginal cultures of 2 among 159 studied, and obtained positive fluorescent smears from stool specimens of 14 of 20 individuals. No positive stool cultures were obtained because of a lack of a selective medium and the overgrowth of *C. hominis* by the enteric bacilli. No isolations or positive smears were obtained from any urine specimens collected (no sample size was given for the urine specimens). These investigators concluded that *C. hominis* is part of

the indigenous commensal respiratory flora and supported this conclusion with the following observations: 1) None of the individuals harboring the organism had any signs or symptoms of disease. 2) Injection of viable suspensions of representative strains into laboratory animals elicited no visible sign of disease. 3) In relation to the high proportion of individuals who harbor the organism, few clinical cases occur. With the exception of these studies, there is a paucity of information concerning the ecology and pathogenicity of these organisms. All recently published information is limited to descriptive case reports of isolation of *C. hominis* from bacterial endocarditis, with the exception of one case report of *C. hominis* meningitis (Francioli et al., 1983). There appear to be no published reports on pathogenicity or virulence mechanisms.

Even though *C. hominis* was originally called a *Pasteurella*-like organism (Tucker et al., 1962), it was soon discovered that it was antigenically unrelated to members of the genus *Pasteurella* as well as to the genera *Brucella*, *Bordetella*, *Moraxella*, *Hemophilus*, *Streptobacillus*, *Corynebacterium*, *Bacteroides*, *Neisseria*, *Escherichia*, *Aerobacter* (*Enterobacter*) and *Lactobacillus* (Slotnick et al., 1964). It was compared to both Gram-negative and Gram-positive organisms because of the Gram-variable characteristics noted by early investigators. Because of this anomalous Gram-stain reaction, the fine structure of *C. hominis* was studied by Reyn et al. (1971). These investigators found that the cell wall was of the Gram-negative type, but an unusual feature of all strains examined was a 20–40-nm thick polar cap. This material was strictly limited to the terminal portion of the cell, adhering to the outside of the cell wall. Profile sections of this cap indicated that it was formed by radial arrangements of tufts of material but subsequent studies employing freeze-etching and negative-staining techniques were unable to further elucidate the nature of this cap material. The other notable feature of the *C. hominis* cell wall was an unusually dense outer layer. This layer was composed of a repeating structure which con-

*This chapter was taken unchanged from the second edition.

sisted of units exhibiting tetragonal or rectangular packing. The periodicity of these arrays measured 5.5 nm; the average diameter of the units was 3.4 nm and the space between them was 2 nm. Surface arrays are more typical of Gram-positive bacteria than of Gram-negative bacteria but are not unknown in the latter (Reyn et al., 1971).

Limited genetic studies have demonstrated that the GC content of the DNA for *C. hominis* is quite different from the other Gram-negative rod-shaped organisms which have similar physiological characteristics. *C. hominis* GC is 59–60%, *Haemophilus aphrophilus* is 42%, *Kingella* sp. is 47.3–54.8%, *Actinobacillus actinomycetemcomitans* is 42.7%, *Pasteurella* sp. is 40–45%, *Eikenella corrodens* is 56.2–58.2%, and *Capnocytophaga* sp. is 33–41% (Weaver, 1984).

Isolation

Except for the studies of Slotnick and colleagues, all published isolation attempts have been from normally sterile sites, predominantly blood. The one recorded isolation from cerebral spinal fluid does not give cultural information (Francioli et al., 1983). *C. hominis*, although a slow-growing organism, appears to be able to initiate growth on a variety of blood culture media under both anaerobic and aerobic conditions. Only two types of basal media were reported not to support primary blood culture isolation attempts—thioglycollate and Schaedler broths (Bruun et al., 1983; Midgley et al., 1970; Piot et al., 1978). Since it has been reported that *C. hominis* growth may not be noted until after 23 days of incubation, the failure to see growth in the above two media may be due to the fact that the cultures were discarded as negative after 14 days of incubation (Geraci et al., 1978). More typically, growth of the organism is seen after 5 to 8 days of incubation. For subculture from primary cul-

tures, 5% sheep blood or chocolate agar are most frequently used although *C. hominis* will grow on media without blood (Midgley et al., 1970). Neither CO₂ or humidity is an absolute growth requirement for all strains, but both supplemental CO₂ and increased humidity enhance growth (Savage et al., 1977).

For isolation from nonsterile sites, no selective medium is presently available. Earlier studies on throat and nose specimens used trypticase-soy agar slants or plates enriched with 5% human blood incubated at 37°C for 48–72 h (Slotnick et al., 1964). Slotnick's subsequent screen of vaginal and cervical swabs for *C. hominis* employed a slightly different method. Swabs were placed in tubes containing 2 ml of Trypticase Soy Broth (BBL) for transport to the laboratory where they were plated on a Casman's blood agar plate and a chocolate agar plate (BBL). Incubation was at 37°C for 4 days in a candle jar (Slotnick, 1968).

Identification

Differential characteristics of *C. hominis* which distinguish it from other similar Gram-negative organisms are given in Table 1. General biochemical characteristics of *C. hominis* are given in Table 2.

Microscopically, cells of *C. hominis* are pleomorphic Gram-negative rods which may show retention of crystal violet in the central portion or in the enlarged ends. Teardrop cells and filaments of varying lengths may occur. One study attributes this extreme pleomorphism and the irregular staining to growth on media without yeast extract. This report states that when *C. hominis* was grown on a medium containing yeast extract, the organisms appeared mainly as uniform Gram-negative rods in contrast to the pleomorphism and Gram-variable characteris-

tics exhibited on media without yeast (Savage et al., 1977).

The Genus *Actinobacillus*

JANET I. MACINNES AND EDWARD T. LALLY

Introduction

Members of the genus *Actinobacillus* are small, Gram-negative, pleomorphic, coccobacillary rods that are facultatively anaerobic, indole negative, -galactosidase and urease positive and reduce nitrates (Olsen and Møller, 2004a). Apart from *A. pleuropneumoniae* and some *A. suis* strains, most *Actinobacillus* isolates grow on MacConkey agar. The optimum temperature for growth is 37°C and all have complex nutritional requirements. These bacteria are always associated with mucous membranes and the host range of *Actinobacillus* spp. tends to be limited. Although members of the genus *Actinobacillus* can be benign commensals of the respiratory, alimentary, and genital tracts, *Actinobacillus equuli*, *A. lignieresii*, *A. pleuropneumoniae* and *A. suis* can cause important diseases in domestic animals. (*Actinobacillus*) *actinomycetemcomitans* is the only member of the genus that routinely colonizes humans; *A. hominus* and *A. ureae* are associated with rare opportunistic infections in compromised individuals.

Phylogeny

When the family Pasteurellaceae was first described in 1981 by Pohl et al., it was comprised of three genera: *Pasteurella*, *Haemophilus* and *Actinobacillus*. Since that time it has undergone considerable revision and two new genera, *Lonepinella* and *Mannheimia* (formerly *Pasteurella* complex) have been added (Osawa et al., 1996; Angen et al., 1999). Recent 16S rRNA studies of more than 120 strains of the family Pasteurellaceae revealed 20 genus level groups (I. Olsen et al., manuscript in press). On the basis of this analysis, the *Actinobacillus* group is comprised of *A. suis*, *A. equuli*, *A. hominis*, *A. ureae*, *A. lignieresii* and *A. pleuropneumoniae*. In addition, several other species/strains including *H. parahaemolyticus*, *Actinobacillus* spp. CCUG 19799 and CCUG 28015R, Bisgaard's taxon 8 CCUG 16494, Bisgaard's taxon 9 CCUG 24862, *Actinobacillus* (*capsulatus*) MCCM 00149 and *H. parainfluenzae* belong to the group *Actinobacil-*

lus minor, *A. porcinus*, *A. rossii* and *A. indolicus* are closely related to the *Actinobacillus* group while (*A.*) *capsulatus*, *A. muris*, *A. seminis* and (*A.*) *actinomycetemcomitans* are only distantly related. When 16S RNA, sequence data, DNA–DNA hybridizations, and phenotypic analysis are considered together, Christensen and Bisgaard (2004) suggest that *Actinobacillus sensu stricto* should be limited to *A. lignieresii*, *A. pleuropneumoniae*, *A. equuli* subsp. *equuli*, *A. equuli* subsp. *haemolyticus*, (taxon 11 of Bisgaard), *A. hominis*, *A. suis*, *A. ureae*, *A. arthritidis* (taxon 9 of Bisgaard), *Actinobacillus* genomospecies 1 and 2 and taxa 8 and 26 of Bisgaard. Further studies using additional strains and other molecular techniques are needed to further clarify the phylogenetic relationships within the genus *Actinobacillus*, but division of the family Pasteurellaceae, and even genera within the family, into phylogenically and phenotypically coherent groups may remain problematic.

Taxonomy

In the ninth edition of *Bergey's Manual of Determinative Bacteriology*, the genus *Actinobacillus* included the 11 species: (*A.*) *actinomycetemcomitans*, (*A.*) *capsulatus*, *A. equuli*, *A. hominis*, *A. lignieresii*, (*A.*) *muris*, *A. pleuropneumoniae*, (*A.*) *rossii*, (*A.*) *seminis*, *A. suis* and *A. ureae*. Four additional species, (*A.*) *delphinicola*, (*A.*) *minor*, (*A.*) *porcinus* and (*A.*) *indolicus* were later proposed (Foster et al., 1996; Møller et al., 1996). On the basis of DNA–DNA hybridization and 16S rRNA sequencing, there is a strong case for the inclusion of *A. equuli*, *A. hominis*, *A. lignieresii* and *A. pleuropneumoniae*, *A. suis* and *A. ureae*, but as noted below in this section, the taxonomic positions of isolates of many of these species is complicated by numerous overlapping genotypic and phenotypic features.

Determining the taxonomic position of (*A.*) *actinomycetemcomitans* is confusing, at best, for it appears that (*A.*) *actinomycetemcomitans* is more closely related to *Haemophilus aphrophilus* and *H. paraphrophilus* than to the type species of the genus *Actinobacillus*, *A. lignieresii*.

Further, it has been suggested that *H. aphrophilus* and *H. paraphrophilus* are not true *Haemophilus* spp. as they do not require X and/or V factor for growth (Kilian, 1976; Olsen and Møller, 2004a). Previous attempts to reclassify (*A.*) *actinomycetemcomitans* have not met with approval, and in the future, (*A.*) *actinomycetemcomitans* will likely be placed in a new genus, which may contain one or more subspecies or even species.

At this point, the taxonomic positions of *A. equuli*, *A. lignieresii* and *A. suis* also seem to be very problematic. In 2002, Christensen et al. (2002b) proposed a new classification scheme for equine isolates of *A. equuli*, which had previously been reported as *Actinobacillus equuli*, variants of *A. equuli*, *Actinobacillus suis*, *A. suis*-like, or Bisgaard taxon 11. On the basis of 16S rRNA and DNA-DNA hybridization studies, they recommended that these organisms be classified as *A. equuli* subsp. *equuli* subsp. nov. and *A. equuli* subsp. *haemolyticus* subsp. nov. The picture has been further clarified by Berthoud et al. (2002), who found that two 16S rRNA groups could be identified and that all hemolytic strains of *A. equuli* contained the *aqx* operon. The presence of the *aqx* operon could not, however, be correlated with either of the phylogenetic groups. Kuhnert et al. (2003) further examined representative *A. suis* and *A. equuli* and concluded that the only way that *A. equuli* and *A. suis* can be differentiated is on the basis of their RTX (repeats-in-toxin) toxins. The inter-relatedness of these organisms has been further demonstrated in recent studies by Christensen et al. (2002a) of equine strains of *A. lignieresii*. They found that these organisms are genetically most closely related to Bisgaard taxon 11 and *A. equuli* subsp. *haemolyticus*. Since no distinguishing phenotypic characteristics allow them to be separated from *A. lignieresii*, they have been designated "*Actinobacillus* genomospecies 1."

Haemophilus pleuropneumoniae was first described in detail by Shope et al. in 1964. Prior to that, organisms causing the same disease had been called "*Haemophilus parainfluenzae*" or "*Haemophilus parahaemolytica*" (Taylor, 1999a). It was finally placed in the genus *Actinobacillus* by Pohl et al. in 1983. On the basis of DNA-DNA hybridization studies, it is clearly a member of the genus. Indeed, the serotype 1 strain (Shope 4044) shares over 70% homology with *A. lignieresii* making it technically a member of the same species (Borr et al., 1991).

Habitat

Members of the genus *Actinobacillus* are generally found as parasites or species-specific com-

mensals of the upper respiratory, alimentary and genital tracts of domestic animals including cattle, sheep, horses, swine, nonhuman primates and man. Although there have been few systematic studies, survival of these organisms in the environment is thought to be poor, and there is no evidence (other than [*A.*] *actinomycetemcomitans*, which can be cultured from Old and New World monkeys and great apes) that they can replicate outside their respective hosts.

(*Actinobacillus*) *actinomycetemcomitans* is a pioneer colonizer of the upper aerodigestive tract of both humans and nonhuman primates where acquisition of the organism is seen at 3–6 months on the tongue and oral mucosa in both humans (Lamell et al., 2000) and captive *M. fascicularis* (macaque monkeys; Beighton et al., 1989). The organism has been isolated from patients with infections of the heart, urinary tract and brain. The bacterium is a member of the HACEK (*Hemophilus* spp., *Actinobacillus* spp., *Cardiobacterium* spp., *Eikenella* spp., *Kingella* spp.) group, which is the most common cause of Gram-negative endocarditis in children (Meyer, 1989; Das et al., 1997). The most studied infection by this organism is localized juvenile periodontitis (LJP; Zambon, 1985) recently renamed "localized aggressive periodontitis," LAP, a destructive disease of the periodontal ligament that affects the first molars and central incisors and results in rapid destruction of alveolar bone and subsequent tooth loss (Armitage, 1999).

Actinobacillus ureae is an uncommon inhabitant of the upper respiratory tract of humans that is associated with rhinitis, sinusitis and chronic bronchitis (Henriksen and Jyssum, 1960). Cases of meningitis, pneumonia, peritonitis and sepsis also have been attributed to this organism. The organism is thought to be a commensal, and the association of *A. ureae* meningitis with skull and facial fractures or subsequent surgery suggests that trauma may create an avenue for infection by this otherwise benign organism (for review, see Kingsland and Guss, 1995).

Actinobacillus hominis is another uncommon commensal of the human upper aerodigestive tract. Originally described as an "*A. ureae*-like" bacterium (Henriksen and Jyssum, 1960), it was later recognized as a distinct species (Friis-Møller, 1981; Friis-Møller et al., 2001). This organism has a predilection for infection of patients with pre-existing medical conditions such as chronic alcoholism, cardiovascular disease, cancers of the aerodigestive tract, and drug addiction.

Actinobacillus equuli is the causative agent of "sleepy foal disease" and "joint ill" in young horses and is occasionally associated with diseases in older horses (Phillips, 1992; Quinn et al., 2002). It is a common resident of the oral cavity

and upper respiratory tract of adult horses (Sternberg and Brändström, 1999). It has also been recovered from feces of healthy horses (Phillips, 1992) and enteric lesions (Al-Mashat et al., 1986). *Actinobacillus equuli* can be transmitted from the mare to the foal via the oral, respiratory, or the umbilical route at or following birth. Although there have been reports of sporadic cases of *A. equuli* in swine (Windsor, 1973) and other species, its presence in healthy animals other than horses has not been documented.

Actinobacillus lignieresii is a common commensal of the mouth and rumen of healthy cattle and sheep. It is the causative agent of "wooden tongue," a chronic disease of the soft tissues of the head and neck characterized by granulomatous lesions, which superficially resemble those of *Actinomyces bovis* (Quinn et al., 2002). Although the presence of *A. lignieresii* has been reported in other species, it would appear that these organisms were other Pasteurellaceae (Bisgaard et al., 1986; Christensen et al., 2002a).

Actinobacillus pleuropneumoniae, in contrast to other *Actinobacillus* spp., often behaves as a primary pathogen. Depending on the serovar and strain of the bacterium and the immune status of the infected animal, *A. pleuropneumoniae* can cause a rapidly fatal and highly contagious acute pleuropneumonia (Sebunya and Saunders, 1983). Animals that survive acute infection may continue to harbor the organism in their tonsils, nasal cavities, and lung lesions (Møller and Kilian, 1990; Taylor, 1999a). Less virulent strains may persist in herds without causing any apparent problems until the animals are subjected to stress (Rosendal and Mitchell, 1983; Taylor, 1999a). Transmission of *A. pleuropneumoniae* by aerosol droplets over short distances or through direct contact with infected pigs has been demonstrated experimentally and in the field (Chiers et al., 2002). Airborne transmission from farm to farm is still a matter of debate, but there is growing evidence that this can occur (Fussing et al., 1998; Taylor, 1999a). Survival outside of the host is considered to be of short duration, but it may last for several days at cool temperatures in organic matter. It has also been reported to survive for 30 days in clean water at 4°C (Taylor, 1999a). Although mice can be experimentally infected, there is no evidence for carriage in animals other than swine (Sebunya and Saunders, 1982).

Actinobacillus suis is an early colonizer of the upper respiratory tract of swine, and it has been reported to be isolated from the genital tract of healthy sows (MacInnes and Desrosiers, 1999; Taylor, 1999b). Traditionally, *A. suis* was associated with the sporadic cases of septicemia and sudden death in young piglets, but more recently

it has been associated with a wide range of clinical conditions (including erysipelas-like lesions, arthritis, pneumonia, metritis, abortion and septicemia) in older animals in high health status herds. Infection with *A. suis* likely occurs via invasion of the upper respiratory tract or less commonly via direct entry to the bloodstream, e.g., through abrasion of the skin or umbilical lesions. Since its original description in 1962, sporadic cases of *Actinobacillus suis* or *A. suis*-like organisms have been reported in a variety of birds and mammals (Phillips, 1984). Although recent studies suggest that many strains from non-porcine sources may not have been *A. suis* sensu stricto; there is good evidence that at least some strains of *A. suis* can infect mammals other than swine (Christensen et al., 2002b; Jeannotte et al., 2002). Despite the ability to cause sporadic disease in other species, no reports have suggested that *A. suis* has a normal habitat outside of swine.

Isolation

Most isolates of the genus *Actinobacillus* can be easily cultured on rich media such as sheep blood, chocolate blood, PPLO (pleuropneumonia-like organism), or brain heart infusion agar. *Actinobacillus suis* and *A. pleuropneumoniae* (with the addition of nicotinamide adenine dinucleotide [NAD]) will generally grow on somewhat simpler substrates such as tryptone-yeast extract (TYE) medium (O'Reilly and Niven, 1986). Some strains of *A. pleuropneumoniae* will grow on Herriott's minimal medium, but not well (Herriott et al., 1970). Selective media such as Phillips selective medium for *A. lignieresii* are needed to isolate *Actinobacillus* from environments with mixed bacterial populations. TSVB agar (40 g of tryptic soy agar, 1 g of yeast extract, 100 ml of horse serum, 75 mg of bacitracin, and 5 mg of vancomycin per liter of agar) is an excellent primary selective medium for (*A. actinomycetemcomitans* that can be used to detect the microorganism in levels as low as 20 viable cells per liter (Slots et al., 1982). Jacobsen and Nielsen (1995) tested four different selective media and found that S-MBA (selective meat and blood agar) containing bacitracin (100 µg/ml), lincomycin (1 µg/ml), crystal violet (1 µg/ml), and nystatin (50 µg/ml) to be most effective for the isolation of *A. pleuropneumoniae* from pig tonsil. Columbia agar supplemented with 3% horse serum, 5% yeast extract, and these same antibiotics has also been used (Chiers et al., 2002). Clindamycin (0.5 µg/ml) has been used to improve the isolation of *A. equuli* from nonsterile sites (Sternberg and Brändström, 1999).

Identification

Members of the genus *Actinobacillus* are small, nonmotile, nonsporulating, pleomorphic rods ($\sim 0.3\text{--}0.5 \times 0.6\text{--}1.4 \mu\text{m}$). Depending on the growth conditions, short bacillary or coccobacillary rods may be interspersed with coccal elements giving rise to a “Morse code” appearance. Cells are Gram negative, but staining may be irregular. On media containing glucose or maltose, long rods up to $6 \mu\text{m}$ may be seen. Colonies are small (1–2 mm) and usually sticky especially on primary isolation, but they often lose this property on subculture. All actinobacilli reduce nitrate, produce alkaline phosphatase, urease (except [*A.*] *actinotomycetemcomitans*), and acid from maltose (Table 1). Members of the genus are indole-, ornithine decarboxylase-, and sorbitol-negative. Growth is improved in an atmosphere of 5% CO_2 . A number of tests used for differentiating *Actinobacillus* from other members of the family Pasteurellaceae have been described by Olsen et al. (2004b; Table 2), but given the overlap in phenotypic properties, identification to species or even to the genus level is sometimes difficult within this family. (*Actinobacillus*) *actinotomycetemcomitans*

This organism can be isolated in the gingival crevice and tonsillar crypts. When grown on TSBV agar, the colonies display a classic star-shaped inner structure. The organism does not produce alkaline phosphatase or urease, making

it quite distinct from other actinobacilli (Fig. 1A, Table 2).

Actinobacillus equuli

Usually isolated from healthy or diseased horses, *Actinobacillus equuli* can be difficult to identify, as phenotypic properties such as hemolysis and the ability to ferment arabinose are variable (Kuhnert et al., 2003). Growth is seen on MacConkey agar. When first isolated, colonies (which are round and grayish) may be rough but become smooth upon subculture. Broth cultures may be extremely viscous. *Actinobacillus equuli* ferments glucose, dextrose, xylose, mannitol, lactose, sucrose, maltose, raffinose, melibiose, and trehalose but not arabinose. It is nitrate-, oxidase- and urease-positive but indole- and esculin-negative (Table 2). Differential identification of hemolytic *A. equuli* from *A. suis* can be done on the basis of esculin hydrolysis and arabinose fermentation reactions. These organisms can also be differentiated on the basis of their pattern of RTX toxins (Table 3). Growth typically occurs at $20\text{--}39^\circ\text{C}$, but some strains will grow at 44°C .

Actinobacillus lignieresii

This organism is usually isolated from characteristic lesions of diseased cattle or sheep. Colonies are usually sticky upon first isolation but lose this

property with subculture. Small glistening colonies develop in 24 hours that are at first pale gray but later become pinkish. Broth cultures are turbid with little deposit. Growth is seen on both blood and MacConkey agar. *Actinobacillus lignieresii* ferments glucose, xylose, mannitol, lactose (late), sucrose, and maltose but not trehalose or melibiose. It is oxidase-, nitrate- and urease-positive but indole- and esculin-negative (Table 2). Growth occurs at 20–39°C; no growth is seen at 44°C.

Phillips Selective Medium for *Actinobacillus lignieresii* (Phillips, 1961; Phillips, 1964)

Phillips* selective medium incorporates an antifungal agent and is prepared as follows:

Prepare a stock solution of oleandomycin phosphate (5 mg/ml) in sterile distilled water, distribute it in 0.2 ml amounts, and store it frozen at –20°C. After thawing, prepare a working solution by adding 9.8 ml of sterile distilled water. Prepare a stock suspension of

nystatin (20,000 units/ml) in sterile distilled water, distribute in 1-ml amounts, and store frozen at –20°C. Both these stocks will store satisfactorily for at least 2 months. Prepare the final medium by adding the antibiotics to horse blood agar to give final concentrations of oleandomycin (1 µg/ml) and nystatin (200 units/ml) as follows:

Hartley's digest agar (see below)	93 ml
Horse blood (oxalated)	5 ml
Oleandomycin phosphate working solution	1 ml
Nystatin stock suspension	1 ml

Melt the agar base and cool to 50°C. Add the blood and antibiotics and pour into sterile Petri plates.

Hartley's Digest Broth (Phillips, 1992)

Ox heart (minced)	3000 g
Distilled water	5 liters
Na ₂ CO ₃ (anhydrous; 0.8% solution)	5 liters
Pancreatin	50 g
HCl (concentrated)	80 ml

Table 3. RTX toxins in *Actinobacillus*.

Operon	Protein, function		Distribution
<i>apxI</i>	C	Activator of ApxI toxin	<i>A. pleuropneumoniae</i> serotypes 1, 5a, 5b, 9, 10, 11; <i>A. suis</i> ; and <i>A. lignieresii</i> (not expressed)
	A	105–110-kDa toxin; strong hemolytic and cytotoxic activities	
	B	Transport proteins for ApxIA and ApxIIA	
	D		
<i>apxII</i>	C	Activator of ApxII toxin	All <i>A. pleuropneumoniae</i> serotypes except 3; <i>A. suis</i> ; and <i>A. lignieresii</i> (not expressed)
	A	103–105-kDa toxin; weak hemolytic and no cytotoxic activity	
<i>apxIII</i>	C	Activator of ApxIII toxin	<i>A. pleuropneumoniae</i> serotypes 2, 3, 4, 6 and 8
	A	120-kDa toxin; no hemolytic but strong cytotoxic activity	
	B	Transport proteins for ApxIII	
	D		
<i>apxIV</i>	ORF1	Required for ApxIVA activity	All <i>A. pleuropneumoniae</i> serotypes; Transport mechanism unknown
	A	200 kDa expressed only in vivo; weak hemolytic activity (+ CAMP reaction)	
<i>aqx</i>	C	Activator of AqxA	In hemolytic strains of <i>A. equuli</i> (sensu lato)
	A	110kDa; strong hemolytic activity, + CAMP reaction	
	B	Transport proteins for AqxA	
	D		
<i>ltx</i>	C	Activator of LtxA activity	In all six serotypes of <i>A. actinomycetemcomitans</i> . Serotype b isolates with a 580bp deletion in the promoter region produce 30–50% more toxins than those that do not have the deletion.
	A	116-kDa cytotoxin	
	B	Transport proteins for LktA	
	D		

Abbreviation: CAMP, Christie, Atkins, Munch-Peterson (a test for co-hemolytic activity).

From data in Brogan et al. (1994), Frey (1995), van Ostaaijen et al. (1997), Schaller et al. (1999), and Berthoud et al. (2002).

Mix the minced meat and water and heat to 80°C. Add the sodium carbonate and cool to 45°C. Add pancreatin and incubate at 45°C for 4 h, stirring frequently. When digestion is complete, add the hydrochloric acid and steam at 100°C for 30 min. Cool to room temperature and add 1 N NaOH (caustic soda) to bring the pH to 8.0. Boil for 25 min to precipitate phosphates and filter while hot. Allow to cool and adjust to pH 7.5. Sterilize by autoclaving at 121°C for 15 min. Prepare horse blood agar by adding 1% agar (Oxoid no. 1) to the digest broth, autoclave to sterilize, cool to 50°C and add 5% oxalated horse blood. Distribute into sterile Petri plates.

Actinobacillus pleuropneumoniae

This bacterium is virtually always isolated from swine either from the lungs or nasal secretions of animals with signs of pleuropneumonia or from the tonsils of apparently healthy animals. Upon primary isolation on blood agar plates with a *Staphylococcus aureus* feed streak, the colonies are small (0.5–1 mm) and surrounded by a zone of β -hemolysis. Colonies, which are grayish white, may be of a waxy or soft glistening type (Fig. 1B). No growth occurs on MacConkey agar. Most strains require NAD (biotype 1) and form satellite colonies immediately adjacent to the feeder streak. *Actinobacillus pleuropneumoniae* ferments glucose, xylose, mannitol, lactose (late), and sucrose but not trehalose or arabinose. It is CAMP- (Christie, Atkins, Munch-Peterson), oxidase-, nitrate-, and urease-positive but indole-

and esculin-negative (Table 2). Differentiation of NAD-independent *A. pleuropneumoniae* from *A. suis* can be done on the basis of mannitol and arabinose reactions and RTX toxin profiles. Growth occurs at 20–39°C but not at 44°C.

Media for the Culture of *Actinobacillus pleuropneumoniae*

5% Sheep Blood Agar with NAD

Dissolve 44 g of Columbia agar base (Difco) and qs to 1000 ml with double distilled H₂O. Autoclave and cool to 45°C. Add 50 ml of defibrinated sheep blood and 10 ml of 10% (w/v) filter sterilized NAD.

Chocolate Blood Agar with NAD

Dissolve 44 g of Columbia agar base (Difco) and qs to 1000 ml with double distilled H₂O.

Autoclave and cool to 55°C. Add 50 ml of defibrinated sheep blood, heat to 65°C for 30 min, cool to 45°C, and then add 1 ml of 10% (w/v) filter sterilized NAD.

TYE (O'Reilly and Niven, 1986)

Tryptone (Difco)	20 g
Yeast extract (Difco)	5 g
NaCl (10 mM)	5.84 g
KCl (10 mM)	0.75 g
Na ₂ HPO ₄ (10 mM)	1.42 g
KH ₂ PO ₄	0.46 g
Glucose (10 mM)	1.80 g
Distilled H ₂ O	950 ml

Adjust to pH 7.4 with KOH (not NaOH). Dilute up to 1000 ml with distilled H₂O. Autoclave and cool to 45°C. Add 1 ml of 10% (w/v) filter sterilized NAD.

Fig. 1. Colonial appearance of actinobacilli on various agar media. A) *Actinobacillus acetomycetemcomitans* on TSVB agar. Courtesy of Dr. Cherng-Hsiung Lai, University of Pennsylvania. B) *A. pleuropneumoniae* CM5 on sheep blood agar. C) *A. suis* on sheep blood agar.

Actinobacillus suis

This species can be isolated from tonsils of healthy swine and from the tissues of sick pigs. Colonies are usually sticky on first isolation and this property increases with prolonged incubation. Older colonies may develop a transparent border giving a “fried egg” appearance. Broth cultures may be viscous. On blood agar, *A. suis* colonies, which are creamy yellow, show β -hemolytic activity (Fig. 1C), but it is usually not as strong as that of *A. pleuropneumoniae* (Van Ostaaijen et al., 1997). Some but not all strains will grow on MacConkey agar. *Actinobacillus suis* ferments glucose, xylose, lactose (late), sucrose, maltose, D-mannose, and trehalose but not mannitol. *Actinobacillus suis* are esculin-, nitrate- and urease-positive but indole-negative (Table 2). The optimum temperature for growth is 37°C.

Preservation

Actinobacilli generally lose their viability after ~5 days of culture on solid media. They can survive for years at –80°C or following lyophilization in various substrates including sterile rabbit serum, 20% peptone, or skim milk with 30% glycerol. Fifty percent survival of *A. pleuropneumoniae* stored at 4°C or at room temperature for almost a month in horse serum plus 0.01% NAD has also been reported (del Rio et al., 2003).

Genetics

Studies of members of the genus *Actinobacillus* have been frustrated by their complex nutritional needs and, until recently, the absence of robust genetic tools (Frey and MacInnes, 1995b). Barriers to the use of “conventional” genetic tools such as Tn5 would seem to include powerful restriction systems and poor expression of selectable markers and other genes. It is not clear whether poor expression is a function of codon usage or failure to recognize promoters from heterologous systems. In recent years, a number of shuttle plasmids have been developed for work with various actinobacilli and other Pasteurellaceae (Table 4), but considerable strain-to-strain variation is seen when working with these vectors. The suicide conjugative plasmid, pLOF/Km, carrying a mini-Tn10 with an isopropyl- β -D-thiogalactopyranoside (IPTG)-inducible transposase located outside the mobile element has proven to be a very useful tool for the generation of defined mutations in *A. pleuropneumoniae* (Tascon et al., 1993). Single-step transconjugation systems were developed for the introduction of unmarked deletions into *A. pleuropneumoniae* (Oswald et al., 1999; Baltes et al., 2003). Although both of these systems were designed for use in *A. pleuropneumoniae*, they also work well in *A. suis* and could conceivably work in other *Actinobacillus* spp.

(Actinobacillus) actinomycetemcomitans

The maintenance of DNA in plasmid form is rare in *(A.) actinomycetemcomitans* and posed an initial obstacle because isolation of a plasmid from *(A.) actinomycetemcomitans* was a necessary step to construct the intergeneric plasmids needed for various genetic transfer systems. Plasmids of various molecular sizes (4–20 kDa) were initially reported in 10 *(A.) actinomycetemcomitans* clinical isolates derived from periodontal lesions of patients with rapidly destructive periodontitis (Olsvik and Preus, 1989). All ten isolates had identical plasmid profiles composed of

Abbreviations: Km^r, kanamycin resistance; Sm^r, streptomycin resistance; Ap^r, ampicillin resistance; Su^r, sulfonamide resistance; Cm^r, chloramphenicol resistance; MCS, multiple cloning site; *A.a.*, *Actinobacillus actinomycetemcomitans*; *A. pp.*: *Actinobacillus pleuropneumoniae*; *H. duc.*: *Haemophilus ducreyi*; *H. flu.*: *Haemophilus influenzae*; and *E. coli*: *Escherichia coli*.

four plasmids with molecular sizes 4–20 kDa. While other investigators have confirmed the presence of plasmids in (*A.*) *actinomycetemcomitans*, the occurrence was at a much lower frequency (LeBlanc and Lee, 1993). Of 39 isolates examined, only two harbored detectable plasmids. One strain contained two plasmids, 1.9 kb and ≥30 kb, and the other strain harbored a single 24-kb plasmid. It was the 1.9-kb plasmid, subsequently designated “pVT736-1,” that has been used as the core element in the construction of a number of shuttle plasmids.

The absence of a selectable phenotype in pVT736-1 initially made it unsuitable for use in a transformation system. This issue was remedied by ligation with *Escherichia coli* plasmids such as pUC19 and pGEM7Zf(–) resulting in chimeric plasmids that were able to replicate in several strains of (*A.*) *actinomycetemcomitans* following transformation by electroporation (Sreenivasan et al., 1991). A recombinant plasmid containing two antibiotic-resistant markers was subsequently developed (Sreenivasan et al., 1991; Sreenivasan and Fives-Taylor, 1994). This plasmid, pDL282, was constructed by insertion of a spectinomycin gene isolated from *Entero-*

coccus faecalis (LeBlanc et al., 1991) into a unique restriction site of pVT736-1. The transformation efficiency of (*A.*) *actinomycetemcomitans* by pDL282 was similar to the parent plasmid. pDL282 has been used to construct a shuttle vector (pAES19) that is composed of the fragment of pDL282 containing the (*A.*) *actinomycetemcomitans* origin of replication and spectinomycin gene and from pUC19, the multiple cloning site, and the *lacZa* reporter gene (Nakano et al., 1996), which allows for colorimetric detection of plasmids with inserts and rapid sequencing using commercially available primers.

The naturally occurring plasmid (pYG10) from *Actinobacillus pleuropneumoniae*, which codes for chloramphenicol resistance, was shown to transform some strains of (*A.*) *actinomycetemcomitans* (Lalonde et al., 1989b; Sreenivasan et al., 1991). A derivative of this plasmid, pYG53, was modified to generate a shuttle vector capable of transforming both (*A.*) *actinomycetemcomitans* and *E. coli* (Lalonde and O'Hanley, 1989a; Brogan et al., 1996). In this construct, the *Km^R* gene from pUC4K was ligated into pYG53 to create pYGK. A “low copy plasmid” (3–4

copies per cell in *E. coli*), pYGK is useful for working with genes that are either unstable or lethal in high-copy-number vectors (Brogan et al., 1994).

Electroporation is an efficient means for transferring genetic material into (*A. actinomycetemcomitans*) using conditions established for *A. pleuropneumoniae* and its naturally occurring plasmid, pYG10 (Sreenivasan et al., 1991; Brogan et al., 1994). Conjugation has also been reported as a means for transporting DNA into (*A. actinomycetemcomitans*). Using incompatibility group P (IncP) plasmid, RK2, as the mobilization plasmid, an *E. coli* harboring IncP was used as the donor in mating experiments with a rifampin-resistant, spontaneous mutant of (*A. actinomycetemcomitans*) as the recipient cell (Goncharoff et al., 1993). The successful transfer of the plasmid resulted in (*A. actinomycetemcomitans*) transconjugates that were both ampicillin- and rifampin-resistant. The frequency of Apr and Rif bacteria were obtained at a frequency of 0.3–0.5 transconjugates per donor cell.

Conjugation has also been used to introduce transposons into the (*A. actinomycetemcomitans*) genome. Insertional mutagenesis using a plasmid containing Tn916, a naturally occurring transposon of Gram-positive organisms, suggested that transformation of (*A. actinomycetemcomitans*) was possible (Sato et al., 1992). Kolodrubetz and Kraig (1994) then employed a suicide plasmid, pUT, to deliver a spectinomycin-resistant Tn5 derivative [mini-Tn5(Sp)] via conjugation from *E. coli* to (*A. actinomycetemcomitans*). Spectinomycin-resistant transconjugates were obtained at a frequency of about 1×10^{-7} per recipient cell, and Southern blot analysis showed that the transposon had inserted into the (*A. actinomycetemcomitans*) chromosome in a random manner in 32 different sites in the 33 exconjugants examined. Integration was stable, as demonstrated by the fact that all of the exconjugants remained spectinomycin-resistant after seven passages on nonselective media.

The genome of *Actinobacillus actinomycetemcomitans* strain HK1651 has been completely sequenced and annotated [NCBI website].

The strain sequenced was isolated from a patient with severe periodontal disease and contains the deletion in the leukotoxin promoter region that results in enhanced leukotoxin expression (Brogan et al., 1994), a characteristic that has been shown to be associated with severe localized aggressive periodontitis. The genome is 2,105,503 bp and is predicted to encode 2,345 open reading frames (ORFs). The G+C content of the genome (44.4 mol%) is similar to other previously sequenced members of the Pasteurellaceae family. In addition to containing six complete copies of the ribosomal RNA operons,

tRNAs representing each of the 20 amino acids have been identified. Annotation of the genome resulted in only 47.8% of the total predicted ORFs being assigned a function with the remaining 52.2% being comprised of conserved hypothetical proteins (32%) and hypothetical proteins (20.2%; A. Gillaspay and D. Dyer, personal communication).

The sequencing of *A. pleuropneumoniae* serovar 1, serovar 7 and two serovar 5 strains is well underway [NCBI website]. These whole genome sequences will be invaluable for physiology and pathogenesis of *A. pleuropneumoniae*, as well as establishing the relationships of these organisms to one another and to other members of the genus and the family Pasteurellaceae.

Epidemiology

(*Actinobacillus*) *actinomycetemcomitans*

This organism is associated with a form of periodontal disease known as localized juvenile (aggressive) periodontitis (LAP). A unique disease relative to other forms of periodontitis, LAP occurs in young people, a group that traditionally exhibits a low incidence of periodontal disease. Second, while most periodontal diseases appear to be polymicrobial infections, the subgingival microbiota in LAP typically demonstrates an unusually high association with a single bacterium, (*A. actinomycetemcomitans*). Zambon et al. (1983) reported that (*A. actinomycetemcomitans*) was cultured from 96.5% of LAP patients, but was recovered in only 15.2% of non-LAP patients (healthy individuals, adult periodontitis patients, and insulin-dependent diabetics). In late adolescence, bone loss decreases or arrests, leaving pathognomonic, arc-shaped bony defects around the permanent first molars and/or the incisors in otherwise healthy individuals (Baer, 1971). Another interesting feature of LAP is that the infection occurs in families. Children with LAP almost always have a parent and/or siblings with the disease. Two models could explain these clinical observations: 1) patients with LAP have a genetic defect that makes them susceptible to (*A. actinomycetemcomitans*) colonization or 2) there is vertical (but not horizontal) transmission of virulent strains of (*A. actinomycetemcomitans*).

Analysis of LAP families suggest that predisposition to the disease may be genetically regulated (Jorgenson et al., 1975; Melnick et al., 1976; Saxen, 1980; Saxen and Nevanlinna, 1984; Boughman et al., 1986; Beaty et al., 1987; Hart et al., 1992). Toward this end, a number of cellular defects have been reported in immune cells from patients with LAP including decreased

chemotaxis (Van Dyke et al., 1981; Sigusch et al., 2001), altered superoxide production (Hurtia et al., 1998; Biasi et al., 1999), decreased Ca^{2+} mobilizations (Daniel et al., 1993), decreased phagocytosis (Sigusch et al., 1992), and defective formyl-methionyl-leucyl-phenylalanine (fMLP)-mediated chemotaxis (Perez et al., 1991; Sigusch et al., 1992), all of which suggest that LAP patients have increased susceptibility to (*A.*) *actinomycescomitans* infections. While most of these hypotheses are both attractive and plausible, they have not stood the test of independent verification.

On the other hand, there is increasing support for the fact that a unique serovar b clone, which is characterized by a 530-bp deletion (Brogan et al., 1994) in the promoter region of the RTX operon, can be isolated consistently from patients with active disease. Using polymerase chain reaction (PCR) techniques, this particular (*A.*) *actinomycescomitans* mutant has been demonstrated in LAP patients from diverse individual and geographic backgrounds such as African-Americans and Caucasians in the United States and Brazilians (Bueno et al., 1998; Haraszthy et al., 2000; Guthmiller et al., 2001), while others have isolated organisms with the same 530-bp deletion from African immigrants in European countries (Haubek et al., 1995; Haubek et al., 1996; Haubek et al., 1997) and demonstrated that this marker is endemically present in (*A.*) *actinomycescomitans* strains isolated from Moroccan children with LAP (Haubek et al., 2001). These data support a model whereby LAP is a vertically transmitted infection of a mutant (*A.*) *actinomycescomitans* to normal individuals.

Actinobacillus equuli

Given the uncertainty associated with the classification of *A. equuli* and *A. equuli*-like organisms, discussion of the epidemiology of this organism is difficult. *Actinobacillus equuli* has long been associated with sporadic cases of disease in horses worldwide. From analysis of ribotyping and biotyping data, the population structure of *A. equuli* appears to be quite heterogeneous (Sternberg, 1998; Sternberg and Brändström, 1999). These findings are consistent with early studies by Kim et al. (1976) where more than 28 different heat-stable, antigenic groups were reported. On the basis of pulsed field gel electrophoresis (PFGE) analysis of 174 strains on 10 different farms in Sweden, no single strain of *A. equuli* seemed to predominate (Sternberg, 1998). The same strain was found in only 1 of 4 mother-foal pairs where *A. equuli* was isolated from both. Reminiscent of *Haemophilus parasuis* in swine, the author further showed that

multiple strains of *A. equuli* were present in the same herd and even in the same animal. In a subsequent study by Sternberg and Brändström (1999) where 112 isolates from clinical cases and healthy horses were evaluated by biochemical typing and ribotyping, there were no clear differences between strains from healthy and diseased animals. The inability to identify a "pathogenic phenotype" may have been due to some limitations of the sampling or reflect that all strains may be opportunistic pathogens. Given the demonstration of hemolytic *A. equuli*, which contains Aqx (a toxin to equine lymphocytes), it is tempting to speculate that these strains have greater pathogenic potential, but no experimental or epidemiological data support this notion at this time (Kuhnert et al., 2003).

Actinobacillus lignieresii

This agent causes actinobacillosis, or wooden tongue, a chronic disease in cattle that can be confused with actinomycosis (due to *Actinomyces bovis*). The organism has a worldwide geographic distribution but clinical cases are generally sporadic (Campbell et al., 1975; Phillips, 1992). Subclinical cases may be overlooked so its distribution and importance may be underestimated. *Actinobacillus lignieresii* has been reported in the oral cavity and pharynx of healthy sheep and cattle, though in some early reports isolates identified as *A. lignieresii* were misclassified (Bisgaard et al., 1986). Similarly, *A. lignieresii* isolates reported in other hosts (e.g., rat, dog and duck) were likely other members of the family Pasteurellaceae. Recent studies of equine strains of *A. lignieresii* reveal that these organisms are genetically most closely related to Bisgard taxon 11 and *A. equuli* subsp. *haemolyticus*. Since no distinguishing phenotypic characteristics allow them to be separated from *A. lignieresii*, they have been designated "*Actinobacillus* genomospecies 1" (Christensen et al., 2002a). Six serovars of *A. lignieresii* have been described (one of which shares crossreactive epitopes with *A. pleuropneumoniae*; Lebrun et al., 1999), but the use of serotyping in epidemiological studies has not been reported. Such a study would be of interest as there is some evidence that particular strains of *A. lignieresii* are more virulent than others (Rycroft and Garside, 2000).

Actinobacillus pleuropneumoniae

The causative agent of porcine pleuropneumonia, *A. pleuropneumoniae* has been reported in all countries where there is intensive swine rearing. Pleuropneumonia often occurs as an epizootic, but it is becoming endemic in many

countries. Two main biovars of *A. pleuropneumoniae* have been described on the basis of their requirement for NAD (Fodor et al., 1989). Biovar 1 strains require NAD, whereas biovar 2 strains can synthesize NAD in the presence of specific pyridine nucleotides or their precursors (Niven and Levesque, 1988). Serodiagnostic tests such as enzyme-linked immunosorbent assays (ELISAs) and the complement fixation test (CFT; Inzana and Fenwick, 2001; Enoe et al., 2002), as well as PCR-based tests (Schaller et al., 2001; Chiers et al., 2002) can be used to monitor the presence of *A. pleuropneumoniae* in swine herds. There are more than fifteen different serovars of *A. pleuropneumoniae*. Thirteen serovars (1–12, 15) of biovar 1 strains and 6 serovars (2, 4, 7, 9, 13, and 14) of biovar 2 have been described on the basis of surface polysaccharide antigens, primarily capsule (Nielsen et al., 1997; Blackall et al., 2002). The chemical structures of all of the capsular polysaccharides (CPS) and O side chains of the lipopolysaccharides are known for serovars K1 to 12 and O1 to 11, and a proposed comprehensive serotyping scheme was based on these two antigens (Beynon et al., 1992). Serovars 1 and 5 have been further differentiated into 1a and 1b, and 5a and 5b, on the basis of minor differences in the polysaccharide structures (Altman et al. 1992; Jolie et al., 1994). Although current data are not available from all countries, the most prevalent serovars in Asia and Australia are 1, 2 and 5. In Great Britain and Europe serovars 2 and 9 are found most often, whereas in Canada, the United States and Mexico, serovars 1 and 5 predominate. Although there are usually 1–3 predominant serovars, in some countries as many as 11 different serovars have been reported (Dubreuil et al., 2000). Recently, untypable strains that do not fall into a single serovar have appeared (B. Fenwick, personal communication). As well, strains that share antigen determinants of more than one serovar have been described (Gottschalk et al., 2000).

Actinobacillus suis

Beginning in the early 1990s, the numbers of reports of severe *A. suis* outbreaks in Canada, the United States, and more recently Australia (MacInnes and Desrosiers, 1999; Taylor 1999b; Wilson and McOrist, 2000) have increased. In conventional herds, *A. suis* is a common commensal, and disease is sporadic. In specific pathogen-free herds, epidemics of severe *A. suis* disease can occur in pigs of all ages when the organism is first introduced. Once herd immunity has been established, however, the number of disease outbreaks decreases (Taylor, 1999b). Early studies of the population structure of *A. suis* revealed very little heterogeneity among *A.*

suis isolates cultured from healthy and diseased swine (Bada et al., 1996; Van Ostaaijen et al., 1997), but later studies by Slavic et al. (2000a) revealed that there are at least two O types of *A. suis*. These authors further demonstrated that O2 isolates were more likely to be associated with severe disease; however, they postulated that it was the CPS rather than the lipopolysaccharide (LPS) that may have been the more important determinant of pathogenesis (Slavic et al., 2000a; Slavic et al., 2000b).

Disease

Actinobacillus actinomycetemcomitans

This bacterium is a pioneer colonizer of the human upper aerodigestive tract, with colonization of the oral cavity occurring early in life when the native flora are being established and before tooth eruption has taken place (Alaluusua and Asikainen, 1988; Lamell et al., 2000; Morinushi et al., 2000; Tanner et al., 2002). To establish an ecological niche, the organism has developed strategies and amassed a diverse and rather impressive array of factors to fulfill its colonizer goal. These include 1) the ability to attach to extracellular matrix proteins (Mintz and Fives-Taylor, 1999) and epithelial cells (Meyer and Fives-Taylor, 1994; Mintz and Fives-Taylor, 1994a); 2) antibiotic resistance (Roe et al., 1995); 3) a bacteriocin (Hammond et al., 1987; Stevens et al., 1987); 4) bone resorption by either endotoxin (Kiley and Holt, 1980; Saglie et al., 1990) or surface-associated material (Saglie et al., 1990; Meghji et al., 1994); 5) a chemotactic inhibitor (Van Dyke et al., 1982; Meghji et al., 1994); 6) a collagenase (Robertson et al., 1982), 7) a cytolethal distending toxin (Shenker et al., 1982; Helgeland and Nordby, 1993); 8) Fc-binding proteins (Tolo and Helgeland, 1991; Mintz and Fives-Taylor, 1994b); 9) an RTX toxin (Baehni et al., 1981); and 10) the ability to invade either cells (Meyer and Fives-Taylor, 1993) or tissues (Christersson et al., 1987; Saglie et al., 1987). True to its pathfinder role, this is the only periodontal pathogen that is able to both survive with and kill human immune cells in co-culture (Baehni et al., 1979b).

A critical part of any virulence strategy begins with an ability to persist—the initial step that leads to colonization. The recent description of the *tad* (tight adherence) locus enables the (*A.*) *actinomycetemcomitans* to form biofilms that are difficult to disrupt. The 12–14 genes that make up the *tad* locus include *flp-1*, a pilin gene (Inoue et al., 1998; Kachlany et al., 2001b) and *tadAB-CDEFG* (Kachlany et al., 2000), which are required for tight adherence and the associated

phenotypes of autoaggregation, rough colony morphology, and fibril production. Homologues of the *tad* loci have recently been implicated in human and animal diseases caused by *Pasteurella multocida* (Fuller et al., 2000a) and *Haemophilus ducreyi* (Nika et al., 2002). The observation that *tad*-like loci are found in other human pathogens, including *Yersinia* spp., *Bordetella pertussis*, *Pseudomonas aeruginosa*, *Corynebacterium diphtheriae* and *Mycobacterium tuberculosis* lend support to the notion that colonization is important in microbial pathogenesis (Kachlany et al., 2001a; Planet et al., 2003).

The leukotoxin (Ltx) is a 116-kDa cytotoxic protein that specifically kills a subset of leukocytes including polymorphonuclear leukocytes and peripheral blood monocytes (Baehni et al., 1979a; Tsai et al., 1979). On the basis of sequence homology (Kolodrubetz et al., 1989; Lally et al., 1989a; Lally et al., 1989b; Kraig et al., 1990), the leukotoxin is a member of the RTX family of pore-forming bacterial toxins (Fig. 2). These toxins are synthesized by a diverse group of Gram-negative pathogens including other actinobacilli (see Table 3). All members of the RTX toxin family, including cytolytic toxins, metalloproteases and lipases, share a common gene organization and distinctive structural features. Although variations do exist, the generic RTX toxin operon consists of four genes that are designated *rtxC*, *A*, *B* and *D* in transcriptional order. RTX toxins require post-translational modification to become biologically active. This activation step is accomplished by fatty acid acylation of the structural *rtxA* gene product and requires the participation of the *rtxC* gene product and an acyl carrier protein (Issartel et al., 1991; Stanley et al., 1994; Stanley et al., 1998). Toxin produced in the absence of RtxC is biologically inactive. RTX toxins do not have canonical signal sequences and are transported from the cytoplasm to the cell surface by transport proteins encoded by the *rtxB* and *rtxD* genes. RTXA contains tandemly repeated nonapeptides that have the consensus sequence GGXGXDX (LIIIVWYIF)X (where G is glycine, D aspartic acid, L leucine, I isoleucine, V valine, W tryptophan, Y tyrosine, F phenylalanine, and X any

amino acid). The number of times this motif is repeated varies, ranging from six to 40 with individual toxins, but its presence is the sine qua non for RTX toxin family membership. RTXB proteins are members of the ATP-binding cassette (ABC) superfamily of transport proteins (Higgins, 1992), and RTXD proteins, which are unique to prokaryotes, belong to the membrane fusion protein family (Dinh et al., 1994).

Although extensive amino acid homology exists among the various RTX cytolysins, the cellular and species specificities remain unique for individual toxins (i.e., [*A.*] *actinomycetemcomitans* leukotoxin [LtxA] kills human monomyelocytes while a related toxin, *M. hemolytica* leukotoxin [LktA] kills bovine lymphoid cells). Studies with series of *ltxA/lktA* chimeric toxin genes showed that a 253-amino acid fragment (residues 688–941) that contains the GGXGXDX(LIIIVWYIF)X repeats is involved in target cell recognition.

The restricted host cell specificity of LtxA and LktA (Shewen and Wilkie, 1982; Strathdee and Lo, 1989) suggests that some, and perhaps all, RTX toxins exert their lethal effects by binding to cell-surface receptors. In addition to direct evidence, a general rule for bacterial toxins is that they possess domains for target cell recognition. Members of the colicin family bind to *E. coli* outer membrane proteins (Parker et al., 1990), *Bacillus thuringiensis* δ -endotoxin attaches to the brush border of insect gut cells (Van Rie et al., 1990), recognition of a heparin-binding epidermal growth factor-like precursor is necessary for diphtheria toxin binding to target cells (London, 1992), and the family of AB₅ toxins (e.g., cholera toxin) bind to cell surface ganglioside lipids (Merritt and Hol, 1995). Believing that the unique specificity exhibited by RTX toxins is due to RTX recognition of a cell surface receptor led to the identification LFA-1 (α L/ β 2, CD11a/CD18) as a receptor for RTX toxins (Lally et al., 1997; Wang et al., 1998; Li et al., 1999; Ambagala et al., 1999). LFA-1 is a leukocyte-specific receptor that mediates cell-cell interactions in the immune system (Stewart and Hogg, 1996; Gahmberg, 1997).

In addition to the leukotoxin, all strains of *A. actinomycetemcomitans* also produce cytolethal distending toxins (Cdt) that interfere with the normal cell cycle progression of lymphocytes resulting in G₂ (the gap after S phase) arrest. The molecule responsible for this activity is *cdtB* gene product, a member of the family. The structural toxin gene, *cdtB*, is part of a three-gene operon in transcriptional order: *cdtA*, *cdtB*, and *cdtC*, which encode polypeptides with molecular masses of 24–35 kDa. While Cdts were first recognized by their ability to cause progressive cellular distension of G₂-arrested epithelial cells

Fig. 2. Canonical RTX (repeats-in-toxin) operon.

that contain a tetraploid complement of DNA. Distension is much less evident in intoxicated lymphocytes. Cdts have also been identified in several enteric pathogens such as: pathogenic *Escherichia coli*, *Campylobacter jejuni*, *Shigella* species, *Haemophilus ducreyi* and now (*A. actinomycetemcomitans* (Pickett and Whitehouse, 1999; Shenker et al., 2000; Shenker et al., 2001).

The combination of Ltx and Cdt provide *A. actinomycetemcomitans* with two very efficient protective mechanisms for dealing with either innate or adaptive immunity during the colonization process. Ltx provides the organism with an efficient “summary execution” capability as a way of dealing with LFA-1-bearing immune cells that include granulocytes, natural killer (NK) cells and macrophages. Cdt is able to nullify the adaptive arm of the immune system by blocking the Achilles heel of adaptive immunity—cell division. Arrest of the cell cycle blocks critical adaptive functions such as clonal expansion and cytokine production.

Actinobacillus equuli

A common resident of the oral cavity of adult horses (Phillips, 1984; Phillips, 1992; Sternberg and Brändström, 1999), *A. equuli* can be transmitted from the mare to the foal via the oral, respiratory, or umbilical route at or following birth. It has also been suggested that the organism can be transmitted in utero. In young foals, *A. equuli* can cause an acute septicemia also known as “sleepy foal disease” (Rycroft et al., 1998; Quinn et al., 2002). In foals less than one month of age, *A. equuli* suppurative nephritis, arthritis, pneumonia, pleuritis or enteritis is frequently seen in association with septicemia. Virtually nothing is known about the virulence factors of *A. equuli*. Like *A. pleuropneumoniae* and *A. suis*, hemolytic strains of *A. equuli*, produce an RTX toxin (Berthoud et al., 2002; Kuhnert et al., 2003; Table 3). This toxin is encoded by the *aqxA* gene, which lies within a typical RTX cluster (*aqxCABD*). It has a predicted molecular mass of 110 kDa and has 9 characteristic glycine-rich nonapeptide repeats. The Aqx A protein most closely resembles the LktA protein of *Mannheimia haemolytica*, whereas the B and D proteins have greater than 90% homology with the ApxIB and D proteins of *A. pleuropneumoniae*. Berthoud et al. (2002) found that the *aqxCABD* operon was present in all hemolytic strains of *A. equuli* (which they designated “*A. equuli*-like”), including two strains from rabbits. In contrast, these genes were absent in non-hemolytic *A. equuli*. In addition to its hemolytic activity, the Aqx A toxin when expressed in *E. coli* had clear cytotoxic activity against horse lymphocytes but only weak cytotoxic activity

against porcine lymphocytes. It is tempting to speculate that the Aqx A toxin may have a role in virulence, but this remains to be tested. It has been generally thought that all *A. equuli* have equal pathogenic potential. Consistent with this, Sternberg and Brändström (1999) reported that it was not possible to distinguish between clinical isolates and normal flora by either ribotyping or phenotyping, though unfortunately hemolytic activity was not evaluated.

Actinobacillus lignieresii

This agent causes actinobacillosis or wooden tongue, a chronic disease in cattle that can be confused with actinomycosis (due to *Actinomyces bovis*), cancers and abscesses due to other organisms (Belschner, 1984). *Actinobacillus lignieresii* has a worldwide geographic distribution, but clinical cases are generally sporadic (Campbell et al., 1975; Quinn et al., 2002). Sub-clinical cases may be overlooked so its distribution and importance may be underestimated. Although there have been no systematic studies to identify the source of infection, it is a likely resident of either the rumen or oropharynx. The disease, which progresses very slowly, is normally limited to the soft tissues of the head and neck, particularly the tongue. Damage to mucous membranes predisposes animals to infection. Typically, multiple abscesses occur on the head and under the jaw and throat region. Small, hard, pus-filled ulcers may be present on the tongue. As the disease progresses, the throat region becomes involved, and the animal cannot retract its tongue. The lymphatic glands of the head and neck are often involved as well, and lesions may be present throughout the body. The lesions in the mouth can eventually lead to starvation, or pressure on the windpipe may lead to asphyxiation. Abscesses around the entrance to the rumen may cause chronic bloating and other digestive disturbances. Although animals mount a detectable humoral immune response to *A. lignieresii*, antibodies do not seem to be protective (Rycroft and Garside, 2000). Despite the fact that *A. lignieresii* and *A. pleuropneumoniae* share more than 70% DNA-DNA homology (Borr et al., 1991), the diseases caused by these organisms are very different. The virulence factors of *A. lignieresii* are unknown. *Actinobacillus lignieresii* carries homologues of the *A. pleuropneumoniae* *apxICA* genes, but promoter sequences are absent and the toxin is not expressed (Schaller et al., 2000).

Actinobacillus pleuropneumoniae

All 15 serovars of *A. pleuropneumoniae* are capable of causing pleuropneumonia, although

some serovars are more virulent than others. Although the dogma was once that pigs that survived infection with one serovar were immune to infection with others, there is now evidence that convalescent pigs are only partially protected from challenge by heterologous serovars (Cruijssen et al., 1995b). The differences in virulence among the serovars may be attributed, at least in part, to the production of different combinations of the Apx toxins with the most virulent serovars producing both ApxI and ApxII (Frey, 1995a; Table 3). Other factors, notably the amount of surface polysaccharide present, may also contribute to differences in virulence both between serovars and also between strains within the same serovar (Rosendal et al., 1985; Bandara et al., 2003). The pace of disease can range from peracute to chronic depending on strain, the immune status of the host, and the number of bacteria reaching the lung (Cruijssen et al., 1995a). During peracute or acute disease, pigs may have a high fever, increased respiratory rate, coughing/sneezing, dyspnea, anorexia, ataxia, vomiting, diarrhea, and severe respiratory distress with cyanosis (Taylor, 1999a).

Early in the disease, neutrophil (PMN) infiltration is marked, while during later stages of the disease, macrophage infiltration is more apparent (Liggett et al., 1987). Severe necrotizing vasculitis leads to hemorrhage in the lung (Serebrin et al., 1991; Fig. 3). The organism can be found within alveolar and interlobular fluid and may spread within the lung via lymph vessels, but bacteremia is rare (Ajito et al., 1996). Animals that survive infection frequently retain focal necrotic sequestra, and chronically infected animals may also harbor *A. pleuropneumoniae* in tonsillar crypts (Sidibe et al., 1993; Fig. 4).

In contrast to *A. equuli*, *A. ligieriesii* and *A. suis*, the pathogenesis of *A. pleuropneumoniae* infection has been extensively studied. Several adhesins have been proposed including capsule, fimbriae, and a 55-kDa outer membrane protein (OMP; Zhang et al., 2000; Labrie et al., 2002; Van Overbeke et al., 2002). As well, factors associated

with nutrient acquisition have also been described. *Actinobacillus pleuropneumoniae* has several mechanisms to overcome iron-limitation in the host. It is capable of utilizing heme compounds (including free heme, hemin, hematin and hemoglobin), as well as porcine transferrin, but not lactoferrin, for growth (Deneer and Potter, 1989; Niven et al., 1989; d'Silva et al., 1995). In addition, *A. pleuropneumoniae* can utilize exogenously supplied hydroxamate siderophores and may also liberate its own as yet uncharacterized siderophore (Diarra et al., 1996; Mikael et al., 2002). All serovars of *A. pleuropneumoniae* are capable of obtaining heme products via production of hemolysins (Frey et al., 1993), and all serovars secrete a high molecular mass protease complex (≥ 200 kDa), which has weak activity against porcine hemoglobin in vitro (Negrete-Abascal et al., 1998; Garcia-Cuellar et al., 2000).

Several high-affinity receptors that bind the various iron chelates at the cell surface of *A. pleuropneumoniae* have been described. These include the TbpA (Tbp1, TfbB) and TbpB (Tbp2, TfbA), proteins for high-affinity binding of porcine transferrin (Gerlach et al., 1992; Gonzalez et al., 1995; Fuller et al., 1998) and FhuA, a receptor for ferric hydroxamate siderophores (Mikael et al., 2002). In a number of Gram-negative bacteria, it has been established that release of the strongly bound iron-complexes from high-affinity outer membrane (OM) receptors and subsequent transport across the OM requires energy that is provided by a TonB-ExbB-ExbD protein complex (Braun and Killmann, 1999; Braun, 2003). Iron-regulated *exbB* and *exbD* genes are present upstream of the *tbpA* and *B* genes, and further the role of the transferrin binding proteins in virulence has been demonstrated (Baltes et al., 2001). By contrast, there are no *exbB* or *exbD* genes linked to *fhuA*, and FhuA does not appear to be required for virulence (Baltes et al., 2003).

As with other Gram-negative bacteria, a periplasmic ABC transport system is thought to mediate passage of iron-carrier complexes to the

Fig. 3. Lungs from pigs with acute pleuropneumonia. Note that the lungs in the bottom right corner are almost normal.

Fig. 4. Lung lobe from pig with chronic pleuropneumonia. Note the extensive fibrin deposits.

cytoplasm (Genco and White Dixon, 2001). In *A. pleuropneumoniae*, two ABC-transport systems have been reported to be involved in transfer of iron across the cytoplasmic membrane (CM). The FhuBCD system is specific for ferric hydroxamate (Mikael et al., 2002). A second periplasmic binding-protein-dependent iron transport system encoded by the *afuABC* genes has been described, but the role of these genes in iron uptake remains to be established (Chin et al., 1996; Braun and Killmann, 1999).

Several other ABC-transport systems have also been described that appear to be involved in the pathogenesis of *A. pleuropneumoniae*, or at least in its survival in the host. Recent signature-tagged mutagenesis studies of *A. pleuropneumoniae* have revealed ABC-transport homologues associated with the uptake of polyamines and sugars. Trace metals are required for survival within pig lungs, but once again, further study is needed to determine their precise role in pathogenesis (Fuller et al., 2000b; Sheehan et al., 2003). As well, the high affinity nickel uptake ABC-transport operon, *cbiKLMQO*, appears to have a role in pathogenesis (Bossé and MacInnes, 2000). The contribution of nickel to virulence of *A. pleuropneumoniae* is likely via its role in urease activity since a mutation within the urease operon leads to a similar level of attenuation. It has been postulated that urease activity could play a role in nutrient acquisition by producing ammonia, a preferred nitrogen source, and data also suggest that urease activity may cause impairment of the local immune response and slightly improve persistence (Baltés et al., 2001; Bossé et al., 2001).

Both macrophages and PMNs can phagocytose *A. pleuropneumoniae* in the presence of convalescent pig serum (Cruijssen et al., 1992; Cullen and Rycroft, 1994), but only PMNs can effectively kill *A. pleuropneumoniae*. *Actinobacillus pleuropneumoniae* produces several factors that may contribute to its ability to survive within macrophages. High-molecular-weight carbohydrates present in the capsule and LPS may participate in scavenging of free toxic oxygen radicals (Bilinski et al., 1991; Ward et al., 1998; Rioux et al., 2000). In addition, SodC may have a role in dismutation of superoxide radicals in phagocytic cells (Langford et al., 1996), but isogenic *sodC* mutants are still capable of causing acute pleuropneumonia in experimental infections (Sheehan et al., 2000). Genes encoding two stress response proteins, DnaK and Trigger Factor, are also reported to be essential for survival of *A. pleuropneumoniae* within the porcine respiratory tract and could be important for survival within macrophages (Fuller et al., 2000b). Ammonia produced as the result of urea hydrolysis may also play a role in intracellular

survival (Bossé and MacInnes, 2000) since ammonia inhibits phagosome-lysosome fusion, as well as elevates intra-lysosomal pH in macrophages, resulting in depression of acid hydrolase activity (Gordon et al., 1980).

Actinobacillus pleuropneumoniae is resistant to the bactericidal effects of normal and immune serum and to complement-mediated opsonophagocytosis (Rycroft and Cullen, 1990; Thwaites and Kadis, 1993; Ward and Inzana, 1994). The main factors contributing to serum resistance by this bacterium are capsular polysaccharide (CPS) and/or LPS (Inzana et al., 1988; Rioux et al., 2000). Strains with thick adherent polysaccharide layers do not prevent activation of complement or binding of C3, but binding of anti-polysaccharide antibodies occurs at a distance from the cell membrane, so that deposition of C9, a component of the membrane attack complex, is limited (Ward and Inzana, 1994). Early studies with an undefined capsule-deficient serovar 1 mutant indicated that capsule was important in survival in the host. Similarly, a capsule-deficient serovar 5 strain with a defined mutation was effectively killed in the presence of normal and immune serum, whereas the encapsulated parent was not (Ward et al., 1998). In contrast, a serovar 1 capsular mutant created by transposon mutagenesis appeared to be fully resistant to killing by normal pig serum (Rioux et al., 2000). In a separate study, expression of LPS O-side chains was shown to be responsible for serum resistance in this serovar 1 strain (Paradis et al., 1999).

Although many of the pathological consequences of *A. pleuropneumoniae* infection have been attributed to LPS, extremely large doses of purified LPS (40–100 mg) are required to induce lesions similar to those found in naturally infected pigs (Fenwick et al., 1986). Furthermore, pigs infected with a mutant of a serovar 1 strain of *A. pleuropneumoniae* lacking ApxI and ApxII, but with normal LPS, did not develop clinical disease or significant lung lesions, suggesting that the contribution of LPS to lesion development may be minimal in the absence of Apx toxins (Tascon et al., 1994).

The major factors involved in impairment of phagocytic function of both macrophages and PMNs are three RTX-toxins (ApxI, ApxII and ApxIII), which are produced in various combinations by the different serovars of *A. pleuropneumoniae* (Frey, 1993; Table 3). At sublytic doses, these toxins impair macrophage chemotactic and phagocytic function but stimulate macrophage and PMN oxidative metabolism (Dom et al., 1992a; Dom et al., 1992b; Tarigan et al., 1994). At high concentrations, ApxI and ApxIII are highly toxic, whereas ApxII is moderately toxic for alveolar macrophages and PMNs

(Kamp et al., 1991; Rycroft et al., 1991; Frey, 1993). The Apx toxins are also associated with direct damage to endothelial cells (Serebrin et al., 1991). The critical role of Apx toxins in development of clinical disease and tissue damage has been confirmed using recombinant toxins (Kamp et al., 1997). Endobronchial inoculation of pigs with either rApxI or rApxIII results in severe clinical disease and lesions indistinguishable from those seen in acutely infected animals, whereas inoculation with rApxII results in few or no clinical signs of disease and only mild lung lesions. Although ApxII appears to contribute only minimally to lesion formation, serovar 7 strains, which produce only ApxII, are capable of causing severe disease with typical lung lesions, suggesting other factors are involved (Frey, 1993; Kamp et al., 1997). Similarly, damage to cultured alveolar macrophages by an ApxII and ApxIII-deficient mutant of *A. pleuropneumoniae* serovar 2 suggests that pathogenesis is complex (Cullen and Rycroft, 1994). Recently, a fourth RTX toxin (ApxIV) was reported to be produced by all serovars of *A. pleuropneumoniae* (Schaller et al., 1999). This toxin is antigenically distinct from the other Apx toxins and is only produced in vivo. *Escherichia coli*-expressing cloned ApxIV, along with an associated upstream ORF, has weak hemolytic and co-hemolytic (CAMP) activities (Schaller et al., 1999). The contribution of this RTX toxin to pathogenesis of *A. pleuropneumoniae* remains to be elucidated.

Apart from producing Apx toxins and LPS, *A. pleuropneumoniae* also secretes proteases into the culture medium that may contribute to the pathogenesis of infection (Negrete-Abascal et al., 1998; Garcia-Cuellar, 2000). Recently, a 24-kDa zinc metalloprotease that is present in all *A. pleuropneumoniae* serovars was cloned and expressed in *E. coli*. The oligomeric, but not the monomeric, form of the recombinant polypeptide cleaved azocoll, gelatin, and actin in vitro. This protease is probably different from the >200-kDa metalloprotease complex described by Negrete-Abascal et al. (1998) that also degrades gelatin, since antibodies against this protein fail to recognize the recombinant 24-kDa protease. Although the presence in convalescent antiserum of antibodies specific to the proteases indicates that they are produced in vivo (Negrete-Abascal et al., 1998; Garcia-Cuellar et al., 2000), their possible contribution to development of pathology has yet to be investigated.

Actinobacillus suis

In conventionally reared swine, *A. suis* is a common commensal organism of the upper respiratory tract and an opportunistic pathogen,

especially in very young animals. In high-health status herds, *A. suis* may not be present and epidemics of severe *A. suis* disease can occur in animals of all ages if the organism is introduced. Once herd immunity has been established, however, the number of disease outbreaks decreases (Taylor, 1999b). In neonates and suckling pigs, *A. suis* can cause an acute and rapidly fatal septicemia where death occurs within 15 h. Affected animals may show signs of cyanosis, petechial hemorrhage, fever, respiratory distress, neurological disturbances, and arthritis. In slightly older animals, the disease tends to be less severe and may be characterized by fever, anorexia, and persistent cough. Although mortality is much lower, these animals are often "poor doers" (i.e., consume large amounts of feed but still appear thin). Erythematous skin lesions, fever, and anorexia/inappetence, abortion, metritis, and meningitis have also been reported in sows. Once in the bloodstream, *A. suis* can form microcolonies on vessel walls that lead to regions of hemorrhage and necrosis. Gross lesions are usually seen in the lungs, kidney, heart, spleen, intestines and skin. The lungs may also be filled with a serous or serofibrinous exudate and superficially look like lungs of animals with pleuropneumonia. Occasionally, animals are seen with an acute necrotizing myocarditis that is reminiscent of mulberry heart disease (MacInnes and Desrosiers, 1999).

In contrast to *Actinobacillus pleuropneumoniae*, relatively little is known about the pathogenesis of *Actinobacillus suis*, in part because there have been no good experimental challenge systems available (Slavic, 2000b). Despite many superficial similarities, *A. pleuropneumoniae* and *A. suis* share less than 50% DNA-DNA homology (Borr et al., 1991). They cause distinct diseases and presumably employ different virulence factors. Although *A. suis* is generally thought to be less pathogenic, it seems better able to invade the bloodstream, and unlike *A. pleuropneumoniae*, it can be isolated from the alimentary tract. To date, no attachment factors have been described for *A. suis*. As with *A. pleuropneumoniae*, fimbriae or surface polysaccharides or OMPs could play a role in attachment, but this remains to be tested. A number of virulence factors associated with nutrient acquisition are also present in *A. suis*. For example, *A. suis* is strongly urease positive and can bind porcine (but not human or bovine) transferrin using TbpA and TbpB. These proteins are virtually identical to those in *A. pleuropneumoniae* (Bahrami et al., 2003). Like *A. pleuropneumoniae*, the *exbB* and *exbD* genes are linked to the *tbpA* and B, but a *tonB* homologue is also present upstream. Except in the case of direct entry in the bloodstream (e.g., via an umbilical lesion), the mecha-

nism of invasion is another area of *A. suis* pathogenesis that is not understood. Once in the bloodstream, capsule and LPS undoubtedly play a role in the survival of the organism. Regardless of their O and K types, all *A. suis* isolates appear to be serum resistant and grow better in the presence of fresh serum than in serum that has been complement depleted (Slavic et al., 2000b). The RTX toxins, ApxI and ApxII, which are virtually identical to those present in *A. pleuropneumoniae*, also likely play a role in the pathogenesis of *A. suis*, but it appears that the genes are expressed at a lower level or that the activated toxin is transported outside the cell less efficiently (Van Ostaaijen et al., 1997). In contrast to *A. pleuropneumoniae*, *A. suis* lacks the *apxIV* genes (Schaller et al., 1999).

Applications

A large number of *A. pleuropneumoniae* vaccines have been developed. Most of the early vaccines were whole cell preparations of multiple serovars. Later, purified Apx toxins and iron-regulated proteins were added to some preparations (Goethe et al., 2000). Particularly when compared with protection through natural infection, protection with these products tends to be incomplete (Furesz et al., 1997). A defined capsular mutant has been licensed for use in the United States (Ward et al., 1998), and several attenuated strains that secrete active or detoxified Apx toxins have been described (Prideaux et al., 1999; Fuller et al., 2000c; Garside et al., 2002), but their use may be limited by regulatory considerations. Genetically inactivated strains (bacterial ghosts) created via expression of a cloned phage lysis gene have also been explored as *A. pleuropneumoniae* vaccines (Huter et al., 2000).

At present, there are no commercial vaccines for *A. suis*; however, autogenous bacterins are thought to be useful (Lapointe et al., 2001). In theory, *A. pleuropneumoniae* vaccines, especially those with Apx toxins, might provide some cross-protection, but this remains to be proven.

The Genus *Francisella*

FRANCIS NANO AND KAREN ELKINS

Introduction

Francisella tularensis is best known as the zoonotic, highly infectious etiologic agent of the human disease, tularemia. There are three recognized species in the genus *Francisella*: *F. tularensis*, *F. novicida*, and *F. philomiragia*. All three species can cause human infections, although *F. novicida* and *F. philomiragia* rarely do. Disease caused by *F. tularensis* can be mild but it usually is acute, severe and febrile; infection with a common North American strain can be life threatening.

Phylogeny

Analysis of the 16S rRNA of *Francisella* species places them in the γ -subclass of the Proteobacteria (Forsman, 1994). All of the *Francisella* are closely related (98.5 to 99.9% sequence identity in the 16S rDNA sequence) and form a group together with *Wobachia persica* (97.85 identity) (Forsman, 1994). Recently, two groups discovered endosymbionts of the tick species, *Ornithodoros moubata* (Noda, 1997) and *Dermacantor andersoni* (Niebylski, 1997) that could be placed in the *Francisella* group by virtue of their 16S rDNA sequence similarity. The bacterium associated with *D. andersoni* could grow in Vero cells and infect rodents experimentally, although no tick-to-mammal transmission was observed. It is reasonable to assume that *W. persica* is misclassified as a *Wobachia* species and eventually will be recognized as *Francisella* species along with the tick endosymbionts.

Taxonomy

Classically, *Francisella* spp. have been classified primarily by their virulence phenotypes. The most virulent form is often called *F. tularensis* type A but is also referred to as *F. tularensis* var. *tularensis*. This strain is found only in North America and is the usual cause of tularemia in

humans. The type B form of *F. tularensis*, sometimes referred to as var. *palaeartctic*, is found throughout the Northern Hemisphere. This strain is less virulent than the type A strain. The type A form has citrulline ureidase and ferments glycerol, whereas the type B strain does not. *F. novicida* can be differentiated from the *F. tularensis* strains by its low virulence in rats, its ability to ferment sucrose, its rapid growth and its less fastidious requirements on agar media (Hollis, 1989; Owen, 1964).

Habitat

F. tularensis and *F. novicida* probably should be considered obligate pathogens. Their fastidious growth requirements make growth outside of hosts unlikely. Many researchers have long considered the natural reservoir for *F. tularensis* type A to be the rabbit. In Europe and Asia, *F. tularensis* type B is most often associated with hares and small rodents. However, these associations are based on the observed transmission of *F. tularensis* to humans, and there may be other, unobserved, carriers of tularemia. One thing is clear: arthropods are simply a mechanical vector for transmission, and there is no transovarian passage of classical *F. tularensis* strains.

Isolation

Because of the highly infectious nature of *F. tularensis*, its isolation usually is attempted only by laboratories equipped to handle level III pathogens. Typically, tissue or blood suspected of being infected is inoculated onto cysteine heart agar (Difco) supplemented with 5% (v/v) horse or rabbit blood or 1% (w/v) hemoglobin. The agar plates are incubated at 37°C, and gray colonies appear in 3–4 days. An environment of 5% CO₂ may help the growth of *F. tularensis* but is not essential. A more reliable method for isolating *F. tularensis* is to inoculate the sample into a mouse.

If *F. tularensis* is present, it will cause severe disease in the mouse and can be easily isolated from the liver or spleen.

It is thought that *F. tularensis* requires cysteine for growth on agar plates, and that *F. novicida* does not. This notion has not been systematically tested, and *F. tularensis* clinical isolates that lack a requirement for cysteine have been found (Bernard, 1994; Clarridge, 1995).

Identification

The primary clue to the identification of *F. tularensis* is its association with a severe, flu-like illness contracted from an arthropod vector or contact with wild animals. Upon isolation, *F. tularensis* can be identified as a Gram-negative, small (0.2×0.2 – 0.7 (μ m) coccobacillus, with fastidious growth requirements. *F. novicida* and *F. philomiragia* cells appear slightly larger than those of *F. tularensis*. Most often, *F. tularensis* is positively identified by the reaction of specific antiserum. Traditionally, clinical laboratories have used hyperimmune, polyclonal antisera for fluorescent microscopy or agglutination. Monoclonal antibodies that react with the O-antigen of the *F. tularensis* lipopolysaccharide (LPS) are equally useful for these techniques. Sufficient DNA sequence information exists to use polymerase chain reaction (PCR) or hybridization with oligonucleotides to identify *F. tularensis*, *F. novicida*, and *F. philomiragia* (Forsman, 1990; Fulop, 1996; Long, 1993). Members of the genus also can be identified by their unusual lipid composition (Jantzen, 1979; Hollis, 1989), which is especially important for the identification of *F. novicida* and *F. philomiragia* inasmuch as reagents to help in their identification are not commercially available. All of the *Francisella* species have C_{18} to C_{26} , saturated and monounsaturated fatty acids, large amounts of $C_{10:0}$, $C_{14:0}$, and $C_{16:0}$ saturated fatty acids, and two hydroxy acids, 3-OH $C_{16:0}$ and 3-OH $C_{18:0}$.

Preservation

Although some strains of *Francisella* can be preserved at -80°C in 10% glycerol, other strains are lysed under these conditions and lose much of their viability. A more reliable preservation approach is to freeze or lyophilize *Francisella* strains in the presence of a 1–2% (w/v) protein-rich solution, such as gelatin or fetal bovine serum, or with an equal volume of sterile skim milk. Preserving *Francisella* strains also can be done for several months at -20°C .

Genetics

Transformation and Genetic Manipulations in *Francisella*

All of the published genetic studies of *Francisella* have been done with the live vaccine strain (LVS) of *F. tularensis* or with *F. novicida*. Researchers have avoided genetic studies of the virulent strains to avoid infection of laboratory personnel and to avoid creating an antibiotic-resistant virulent strain. DNA can be introduced into *F. tularensis* LVS and into *F. novicida* via electroporation or chemical transformation (Anthony, 1991b; Tyeryar, 1970a; Tyeryar, 1970b). When *F. tularensis* is electroporated with cloned *F. tularensis* DNA interrupted with an antibiotic marker, the marker is rescued by the homologous recombination of the cloned DNA into the chromosome. The highest frequencies that have been observed are about 6,000 transformants per microgram of DNA. An *E. coli*-*Francisella* shuttle plasmid was constructed by joining parts of a plasmid found in an *F. novicida* strain with the origin of replication of pACYC184 (Norqvist, 1996; Pavlov, 1996). The plasmid can be introduced into *F. tularensis* LVS using a cryotransformation procedure (Mokreivich, 1994).

F. novicida can be transformed (Tyeryar, 1970a, 1970b) after growth in a defined medium (Chamberlain, 1965) and treatment with calcium. A stretch of *Francisella* DNA containing an antibiotic-resistance marker is rapidly integrated into the *F. novicida* chromosome (Anthony, 1991b). Transformation frequencies of approximately 100,000 per microgram of DNA were observed for circular DNA, and transformation frequencies of greater than one million per microgram of DNA were observed for linear DNA. Typically, linear DNA transforms at a much higher frequency. Broad host range plasmids carrying a *Francisella* insert can be found to replicate autonomously in *F. novicida* (Anthony, 1991b; Pomerantsev, 1991). With the exception of plasmid Sa, no DNA has been introduced and maintained by *F. tularensis* or *F. novicida* unless it contained some *Francisella* sequences. Attempts to introduce broad host range plasmids or transposons into *F. tularensis* or *F. novicida* by electroporation or chemical transformation have failed unless *Francisella* DNA cloned into the plasmid or physically linked to the transposon. The data suggest that transforming DNA needs homologous *Francisella* sequences for uptake or maintenance of the DNA. Despite the difficulties in defining the mechanism of DNA uptake, the high frequency transformation of *F. novicida* has allowed the development of methods for random transposon

mutagenesis, merodiploid formation, and gene fusions (Baron, 1998; Baron, 1999a; Mduli, 1994).

All *Francisella* strains tested express a naturally occurring β -lactamase. Most type B strains of *F. tularensis* are resistant to erythromycin, and most type A strains and *F. novicida* are sensitive to erythromycin. All strains are apparently sensitive to chloramphenicol, tetracycline and aminoglycosides, and these sensitivities allow for the use of antibiotic-resistance markers. Both *F. novicida* and *F. tularensis* LVS have been mutagenized with a mini-Tn10 carrying the kanamycin resistance marker from Tn903. To date, the most useful transposon for mutagenesis of *F. novicida* is a Tn1721-based minitransposon, TnMax2, which carries an erythromycin resistance cassette (Haas, 1993). A minicassette and a minitransposon were derived from TnMax2, which allow chloramphenicol acetyltransferase transcriptional fusions to occur in *F. novicida* (Baron, 1999a). All of these experiments relied on mutagenesis of *Francisella* DNA in *E. coli* and subsequent integration into the *Francisella* genome.

Identified Genetic Loci and Sequenced Genes

A handful of loci have been molecularly cloned from *Francisella* and cognate insertion mutants created. An *F. novicida* *recA* mutant has been made, and it is unable to integrate DNA into its chromosome (Berg, 1992). A gene encoding an outer membrane protein, FopA, has been inactivated (Anthony, 1991b). An *F. novicida* *minD* insertion mutant was constructed and found to be sensitive to complement and oxidative radicals (Anthony, 1994). When this mutant was introduced into macrophages, viable numbers of the mutant dropped sharply, presumably from the oxidative burst, and then grew normally. A locus that appears to be needed for detergent and complement resistance, *valAB*, has been identified in *F. novicida* (Mduli, 1994). Using an allele that encodes a temperature sensitive form of ValA, researchers demonstrated that this locus is needed for the assembly of LPS (McDonald, 1997). Cumulative evidence from different publications suggests that ValA and its homologues are ABC transporters responsible for transport of lipid A across the inner membrane. The Val B molecule (called LpxK or OrfE in *E. coli*) is a lipid A 4'-kinase (Garret, 1997). All *Francisella* strains tested have a respiratory burst-inhibiting acid phosphatase, AcpA (Reilly, 1996). Inactivation of the encoding gene does not lead to loss of virulence in *F. novicida*. There is a second acid phosphatase in *F. novicida* that is not found in other *F. tularensis* strains (Baron, 1999b).

An apparent global regulator operon, *mglAB*, is needed for *F. novicida* intracellular growth and virulence (Baron, 1998). To date, this is the only locus in *Francisella* that has been definitively associated with a virulence phenotype. A mis-sense mutation in *mglA* or insertional inactivation of *mglA* or *mglB* results in complete loss of the ability of *F. novicida* to grow inside macrophages. Complementation of the mutated *mglAB* with a wild-type form restores the ability of *F. novicida* to grow in macrophages. Inactivation of *mglAB* leads to loss of expression of several proteins, including a secreted 70-kDa protein.

One study examined the change in protein expression upon infection of macrophages by *F. tularensis* (Golovliov, 1997). A few proteins showed a small increase in expression within 24 hours after infection. Most notable was a 23-kDa protein. This protein also is induced by exposure of *F. tularensis* to hydrogen peroxide. The protein is localized in the cytoplasm, suggesting that it is a stress-induced protein that may be involved in gene regulation. It has no significant similarity to proteins of known function.

The DNA sequences of a handful of other genes have been described, but their role in *Francisella* virulence has not been studied. A combination of groups has embarked upon sequencing the entire genome of *F. tularensis*, Schu4, a highly virulent isolate. As of summer 1999, approximately 9 million bases had been sequenced, which can be accessed from the *Francisella* genome (<http://www.medmicro.mds.qmw.ac.uk./ft/>). Because the *Francisella* LVS genome appears to be about 2.5 Mb, it is likely that most of the *Francisella* genome is already sequenced. If the Schu4 strain genome is of similar size to that of the LVS strain, then one can expect that a great deal of information will be available soon about the *F. tularensis* genome.

Variation in *F. tularensis*

In the 1950s Eigelsbach and colleagues identified spontaneous colony variants of *F. tularensis* that differed in appearance, immunogenicity, and virulence (Eigelsbach, 1951). Variants that were low in immunogenicity and virulence appeared "gray" when viewed through a dissecting microscope using oblique lighting; the wild-type colonies appeared as light blue. The difference is used to evaluate preparations of the tularemia vaccine. Vaccine preparations that contain significant numbers of "gray" variants are poorly immunogenic and not appropriate for human vaccination.

Recent work suggests that the basis for the change in colony morphology can be attributed to a shift in the amount and type of O-antigen produced (Cowley, 1996). The "gray" variants

appear translucent on blood agar plate and produce less of the usual *F. tularensis* O-antigen. Accompanying the lower expression of the *F. tularensis* O-antigen is a newly expressed O-antigen, of the type normally found on *F. novicida*. The change in O-antigen is coincident with a change in the ability of the LPS to induce nitric oxide production and for *F. tularensis* to grow in rat macrophages. These phenotypic changes are reversible and occur in one step. The genetic basis for these changes is not known but may become evident when the *Francisella* genome project is completed.

Epidemiology

Virtually all available epidemiological information concerns *F. tularensis*. *F. novicida* ("new killer") has been isolated only in the United States, once from water collected near dead muskrats in Utah (Larson, 1955) and twice as a human pathogen from patients with a tularemia-like illness (Hollis, 1989). The other species, *F. philomiragia*, originally was isolated from muskrats and water during an attempt to reisolate *F. novicida* (Jensen, 1969); this bacterium, named because of frequent mirages seen in the area, has been associated with an acute febrile disease in near-drowning victims and in patients with chronic granulomatous disease (Wenger, 1989; Sicherer, 1997). To date, 13/14 *F. philomiragia* isolates were from the United States, the other was from Switzerland (Wenger, 1989).

F. tularensis originally was isolated by McCoy and Chapin (McCoy, 1912) following outbreaks of a plague-like illness among ground squirrels in Tulare County, California. The agent responsible for this disease in rodents was also responsible for human illnesses, variously called lemming fever, deer-fly fever, rabbit fever, and tick fever in the United States. A similar clinical syndrome recognized among people who ate rabbit meat in Japan was called Ohara's disease (Francis, 1925; Francis, 1928; Ohara, 1954). As implied by several of these early names, *F. tularensis* is carried by both arthropod vectors (such as ticks and deer flies) and by many species of vertebrates. Specifically, *F. tularensis* has been isolated from over 50 arthropod species, including a wide variety of ticks that live in association with wildlife and domestic animals. Further, *F. tularensis* has been isolated from over 100 types of wildlife; the most important animal reservoirs include rabbits, hares, mice, rats, muskrats, beavers, and voles. Tularemia has been diagnosed in, and acquired from, domestic cats as well (Capellan, 1993). Those most often afflicted with tularemia include hunters, hikers, and others who are exposed to wild animals and their arthropod par-

asites. Understanding the distribution of *Francisella* in nature is, therefore, key to appreciating its biology as well as its potential as a human clinical problem.

F. tularensis causes disease in virtually all its animal hosts, although incubation times and severity of symptoms vary widely. Not surprisingly, infected wild animals that are ill may come in contact with humans, with the end result being transmission of disease from animal to human. Person-to-person transmission occurs rarely, if ever. However, well-investigated outbreaks of pneumonic tularemia in Martha's Vineyard (Teutsch, 1979) and in Sweden (Dahlstrand, 1971) also demonstrate that tularemia occasionally can be transmitted by aerosol. In Martha's Vineyard a cluster of cases occurred in vacationers who were all exposed to the same indoor fire, while in Sweden a large outbreak occurred among farmers who inhaled dust from infected hay.

There are two seasonal peaks of *Francisella* infections. Disease diagnosed in the spring or early summer often is associated with tick or mosquito bites, when human outdoor activity and insect exposure are at their highest. Outbreaks of disease in the winter often are most associated with hunting.

Since its original description in the United States, *F. tularensis* has been isolated regularly in Canada, several states of the former Soviet Union, Sweden, Finland, Norway, Italy, Austria, Czechoslovakia, Hungary, and Japan. Virtually all isolates have been found in northern latitudes between 30 and 71°. Over 22,000 cases of tularemia were diagnosed in the United States between 1927 and 1948, with a case fatality rate of about 8% (Sanford, 1983); in the last three decades, however, only 100–300 cases per year are reported in the United States, with dramatic drops in case fatalities since the introduction of antibiotic treatment. The reasons for the decline in the overall number of cases in the United States since the 1950s are not clear but may be related to changes in housing patterns and in interaction with the relevant wildlife, either in the recreational or peri-residential environment.

Nonetheless, several well documented recent outbreaks of tularemia in the United States serve to illustrate the epidemiology of the disease in North America (Young, 1969; Brachman, 1969). Tularemia has been a reportable disease in the United States for several decades but had never occurred in Vermont until the spring of 1968. A cluster of tularemia cases in residents who had influenza-like symptoms with hand sores and lymphadenopathy was recognized in Vermont in early 1968. All cases had handled muskrats trapped from three streams in Addison County. Once the outbreak was appreciated, thorough

epidemiological investigation revealed a somewhat unexpected clinical picture. Thirty-nine symptomatic cases were identified, but the distribution between clinically mild, moderate, and severe disease was approximately even (11, 13, and 14 cases, respectively). This contrasts with the usual concept of tularemia as a severe systemic illness in all persons infected with the same virulent strain (which is assumed in this localized outbreak), suggesting large differences in host susceptibility to disease. In addition, serological screening of area residents who had contact with muskrats resulted in detection of eight apparently asymptomatic cases. *F. tularensis* subsequently was cultured from about 5% of captured muskrats in the area (but not from rabbits or from the ectoparasites combed from the muskrats), as well as from mud and water in the streams in question. Studies of the isolates from both dead muskrats and mud indicated that these were type B bacteria (Hornick, 1969), which are generally considered to be consistent with mild but not more severe disease. The means by which *F. tularensis*, which was clearly not endemic in the area, was introduced to Vermont could not be determined. Thus this investigation demonstrates both the importance of identified contact with host animals and the broad range of clinical outcomes possible following infection.

Tularemia was recognized in the Soviet Union in the late 1920s and became a significant public health problem during the years of World War II. Approximately 100,000 cases occurred between 1940 and 1945, as sanitation and population movements changed; the disease became endemic in voles and field mice. Live attenuated tularemia vaccines were developed by the Gamaleia Institute in the former Soviet Union in the 1940s, and several mass vaccination campaigns were undertaken between 1946 and 1955 (Sandström, 1994). This appears to have resulted in dramatic declines in numbers of annual cases, which are now on the order of a few hundred cases a year.

In the United Kingdom, the few reported cases of tularemia were patients who returned from travel elsewhere (Blomley, 1972; Wood, 1976), which suggests that *F. tularensis* is not enzootic in animals of the British Isles.

Disease

Virulence Factors of the Bacterium

The possible mechanism(s) of *Francisella* pathogenesis in animals or humans have been studied only for *F. tularensis* and the related attenuated vaccine strain (*F. tularensis* LVS). No secreted

toxins or other protein virulence factors of *F. tularensis* have been identified to date. Although all strains of *F. tularensis* are Gram negative and have an LPS, the molecule essentially lacks traditional endotoxic activity, as well as a number of immunomodulatory activities, including stimulation of tumor necrosis factor (TNF) alpha production (Sandström, 1992; Ancuta, 1996). The only consistent virulence factor identified to date is the bacterial capsule (Hood, 1977). Methods were developed for removing capsule from the virulent *F. tularensis* strain Schu S4 and were used to demonstrate that the resulting viable bacteria were less virulent (LD_{50} reduced about 100-fold) in guinea pigs but not in mice. Electron microscopy demonstrated both the initial presence of a capsule and its removal following treatment, but it remains possible that other bacterial factors were affected by treatment. The capsule itself was neither toxic nor immunogenic, suggesting that its role in virulence was related more likely to protection of the intact bacteria against host defenses. Similarly, loss of capsule by *F. tularensis* LVS, through manipulation of culture conditions, resulted in bacteria with lowered virulence in mice (Cherwonogrodzky, 1994). More directly, a capsule-deficient mutant of *F. tularensis* LVS, derived by chemical mutagenesis, was much less virulent than the parent strain in outbred mice (Sandström, 1988). The loss of virulence was probably due to increased sensitivity of the mutant (designated LVSR) to killing by serum through activation of the classical complement pathway. Paradoxically, LVSR also was less susceptible to intracellular oxygen-dependent killing by human polymorphonuclear leukocytes (PMNs), suggesting that host recognition of the capsule also was responsible for activation of PMNs. Other research (Cowley, 1996) demonstrated that LVSR also lacked much of its LPS O antigen, which may be the basis for serum sensitivity. *F. novicida*, which apparently does not have a capsule, is nonetheless resistant to the bactericidal action of serum; in contrast to LPS from *F. tularensis*, however, LPS purified from *F. novicida* appears to be endotoxic and may retain the ability to stimulate nitric oxide production from macrophages (Cowley, 1996). The relationship, if any, of endotoxin activity to disease produced by *F. novicida* is unknown.

Disease progression and pathology have been described in monkey models of aerosol infection with both Type A (White, 1964) and Type B (Schricker, 1972) *F. tularensis*. Even though monkeys appear somewhat more susceptible to *Francisella* infection, the course of disease in monkeys parallels that in humans. Infected monkeys exhibited an acute febrile illness with pneumonia when bacteria were introduced by aerosol. Bacteria multiplied readily in the lungs,

disseminated to regional lymph nodes, and then spread to spleen and liver; surviving animals cleared bacteria within 2 months. The cause of death in lethal cases, however, was not specifically determined, but was generally assumed to follow overwhelming bacterial burden and liver failure. Specific bacterial virulence factors responsible for disease progression, however, were not identified.

Host Response, Immunity, and Vaccination

Since *Francisella* is a facultative intracellular bacterium, its ability to cause disease is probably most directly related to host responses following infection of macrophages and macrophage-like cells in organs of the reticuloendothelial system (spleen, lymph nodes, liver, and lung). Thus, pathogenicity is best considered in relationship to the interaction of the bacterium with host cells and tissues. The immunology of *Francisella* infection has been reviewed in some detail elsewhere (Tärnvik, 1989), and thus this section will focus on more recent developments. In general, it is worth noting that most nonvaccinated laboratory workers who handle virulent tularemia eventually become infected and suffer the disease. Dr. Francis himself had, and documented carefully, four distinct episodes of *F. tularensis* infection in the course of 20 years of studying the bacterium. This, as well as a handful of other documented cases of reinfection, raises the question of whether primary infection effectively generates specific protective secondary immunity. It is highly likely, however, that examples of reinfection are the exception rather than the rule. Other studies do indicate development of long lasting protective immunity following natural infection, and documented cases of reinfection are rare (Burke, 1977). Thus reinfection after primary infection most likely occurs only after exposure to particularly large and overwhelming doses, such as Dr. Francis might have received. For obvious practical reasons, however, researchers have preferred to use attenuated strains of *Francisella* rather than virulent strains, and thus a great deal of the current literature on *Francisella* concerns study of LVS, the live vaccine strain of *F. tularensis*. Similarly, much of what is inferred about the immunology of *Francisella* derives from study of the animal immune response to LVS.

Infection of mammals with *Francisella* initiates a cascade of nonspecific and specific host responses. As with most bacterial infections, PMNs are recruited to the site of *Francisella* infection within hours after entry. However, attenuated strains such as LVS were much more susceptible to killing by PMNs than wild-type strains, even though both are encapsulated

(Löfgren, 1983). In mice infected intravenously with *F. tularensis* LVS, bacteria initially infected Kupffer cells in the liver but also infected adjacent hepatocytes. It appeared that PMNs also recognized and killed infected hepatocytes, thus releasing bacteria for conventional phagocytosis and direct killing by PMNs (Conlan, 1992). If PMNs were not available, unrestricted bacterial growth continued in hepatocytes (which lack intracellular killing mechanisms), resulting in rapid death of the animal. Specific mechanisms of susceptibility or resistance to PMN-mediated killing of *Francisella* have not been determined, however.

Francisella cells that escape early killing by PMNs infect and grow readily in resident mammalian macrophages. Both *F. tularensis* LVS and *F. novicida* multiply in macrophages isolated from mice and guinea pigs. Unlike LVS, however, *F. novicida* does not grow in rat macrophages (Anthony, 1991). This apparently is because LPS stimulates rat macrophages to produce nitric oxide, which in turn ablates intracellular growth of the bacterium (Cowley, 1996). Both LVS and *F. novicida* occupy a membrane-bound compartment that appears to be a phagosome that is not fused with lysosomes (Anthony, 1991). Growth of LVS in mouse macrophages further requires an acidified compartment that permits availability of iron (Fortier, 1995). Intracellular growth further requires a two-cistron bacterial operon, designated *mgLAB*; inactivation of the operon results in decreased expression of many bacterial proteins, as well as in lost capacity to grow in macrophages and reduced virulence in mice (Baron, 1998). Surprisingly, a relatively small number of changes were found in host protein expression by macrophages following *Francisella* infection (Golovliov, 1997).

Killing of *F. tularensis* LVS by activated murine macrophages has been demonstrated. Mouse macrophages deliberately activated by treatment with interferon (IFN) gamma readily controlled the intracellular growth of *F. tularensis* LVS by both nitric oxide-dependent and nitric oxide-independent means (Anthony, 1992; Fortier, 1992; Polsinelli, 1994), although it is not completely clear whether the activity is actually bactericidal or simply bacteriostatic. Manipulations that limited availability of IFN or nitric oxide production in animals clearly increased the relative virulence of LVS, while those that activated macrophages increased host resistance (Leiby, 1992; Green, 1993). Thus, the state of host phagocyte activation has a clear effect on the severity of disease produced in mice by LVS.

Macrophage activation for control of growth probably occurs as a consequence of both innate and specific immune responses. Over the last decade, studies of several intracellular pathogens

such as *Listeria monocytogenes*, *Salmonella typhimurium* and *Leishmania* have indicated that mammals have an initial early (days to weeks) lymphocyte-independent, innate immune response phase and a later (weeks to months) lymphocyte-dependent, adaptive immune response phase of resistance to primary infection. *Francisella* appears to be no exception. Thus, both T cell deficient, athymic *nu/nu* mice (Elkins, 1993) and total lymphocyte-deficient *scid* mice (Elkins, 1996) are able to control and survive primary infection with LVS for 3–4 weeks before succumbing. As discussed, the activity of PMNs is necessary for initial survival of LVS infection in mice (Sjöstedt, 1994; Elkins, 1996). Similar to other intracellular infections, the survival of LVS infection for more than a week clearly is dependent on the production of the Th1-like cytokines IFN γ and TNF α (Anthony, 1989; Leiby, 1992; Elkins, 1992b; Elkins, 1993; Elkins, 1996). TNF α , IFN γ , IL-10, and IL-12 messenger RNAs and the corresponding cytokine proteins (but not IL-2, IL-3, or IL-4) were detectable in livers from mice within 24–48 hours of subcutaneous sublethal infection with LVS (Golovliov, 1995), as well as following lethal infection with virulent tularemia (Golovliov, 1996). Activated macrophages and natural killer cells, not lymphocytes, probably produce these cytokines, although direct demonstration of the cellular sources awaits further study. Further, the stimulus for activation of macrophages and natural killer cells obviously does not proceed through specific-receptor mediated recognition of *Francisella*-related molecules but presumably requires recognition of determinants common to pathogens. Bacterial cell wall polysaccharides, capsular polysaccharides, lipopolysaccharides, and unmethylated DNA containing CpG dinucleotides have been proposed as ligands for common “pattern recognition” receptors on cells such as macrophages and natural killer cells of the innate immune system (Janeway, 1992). Elucidation of such putative structures on *Francisella* awaits further study, although recent investigations indicate that bacterial DNA preparations, either oligonucleotides or genomic DNA purified from LVS, are capable of stimulating protection against lethal LVS infection in mice (Elkins, 1999b).

Another potential bridging mechanism between innate and specific immunity in *Francisella* infection has been proposed (Elkins, 1992a; Elkins, 1993; Culkin, 1997). Normal mice given a sublethal infection with LVS are, very surprisingly, strongly resistant to a second lethal LVS infection that is introduced only 2–3 days later. This resistance mechanism appears to be dependent on lymphocytes and especially B cells. Athymic *nu/nu* mice, T cell-depleted mice, and

all T cell knockout mice are able to survive double infection, but *scid* mice and B cell knockout mice are not (Elkins, 1992a; Elkins, 1993; Conlan, 1994; Culkin, 1997). This early protective response probably is not, however, related to B cell-mediated production of specific antibodies. This mechanism is nonspecific and operative in *Listeria monocytogenes* infection as well (Elkins, 1998). Because oligonucleotide DNA containing unmethylated CpG motifs stimulates protection against both lethal LVS and *Listeria* infection in mice (Elkins, 1999b), early protection may be a consequence of host recognition of released bacterial DNA shortly after infection.

Effector mechanisms of the innate immune system may be necessary prerequisites to the development of specific secondary immunity; thus macrophage activation, neutrophil activation, natural killer cell function, and cytokine production may be required not only to control initial infection but also to promote development of specific, lymphocyte-mediated immunity. It should further be remembered that in any second exposure to the bacteria, a concomitant innate immune response is again elicited, just as in primary infection, and these effector mechanisms may be quite important in both initiating and augmenting specific T cell-mediated responses. For example, it has been shown that PMNs contribute significantly to survival of secondary LVS infections in mice (Sjöstedt, 1994).

Long-term resolution of primary *Francisella* infection clearly requires the activity of conventional T lymphocytes because neither *nu/nu* mice (which have B cells) nor α/β T cell knockout mice survive more than a month after LVS infection (Elkins, 1993; Conlan, 1994; Yee, 1996). In total T cell-deficient mice, bacterial numbers in organs quickly reach a plateau level several days after infection; this steady-state level is maintained over several weeks in apparently asymptomatic mice, until bacterial numbers begin a precipitous rise shortly before death of the animal (Elkins, 1993). The B cell knockout mice appear only slightly impaired in their ability to survive and clear a primary intradermal LVS infection (Elkins, 1999a). On the other hand, mice deficient in mature B cells and antibodies (B cell knockout mice) were 100-fold less well protected against secondary lethal challenge than were their normal counterparts. This defect in optimal specific protective immunity was readily reconstituted by transfer of primed, and to a lesser degree, unprimed B cells but not by transfer of specific antibodies (Elkins, 1999a). Thus, B cells appear to have a significant role in optimal secondary immunity to LVS in mice, through a function other than antibody production. Either CD4⁺ T cells or CD8⁺ T cells are apparently sufficient to effect survival, as knockout mice defi-

cient in only one T cell subset are readily able to clear primary intradermal LVS infection (Yee, 1996; see also Conlan, 1994). The specific effector function contributed by T lymphocytes, over and above cytokine production that probably contributes to macrophage activation for control of intracellular bacterial growth, remains to be revealed. The T helper cell function that is part of specific antibody production is unlikely to be critical, since CD4⁻ knockout mice that fail to make specific IgG anti-LVS antibodies easily resolve primary (and secondary) LVS infection (Yee, 1996). In other systems, T cells have been shown to function as cytotoxic cells against bacteria-infected macrophages (Kaufmann, 1988). Inasmuch as macrophages activated by IFN γ appear to control (but not necessarily completely clear) bacterial numbers (Anthony, 1992; Fortier, 1992; Polsinelli, 1994), the concept of final elimination of bacteria by T cell-mediated killing is attractive. In fact, a recent study described restimulated CD4⁺ cytotoxic T cells from peripheral blood lymphocytes (PBLs) of humans vaccinated with LVS that were specific for *F. tularensis*-pulsed monocytes (Surcel, 1991b).

The contribution of $\gamma\delta^+$ T cells to primary infection may be minimal because the ability to survive and clear primary infection in both knockout mice deficient for the delta chain of the T cell receptor (and thus lacking $\gamma\delta^+$ T cells) and normal mice appeared to be comparable (Yee, 1996). However, some deficiency in their ability to survive maximal secondary infection was observed: *Francisella*-immune Tcr δ knockout mice had difficulty surviving maximal lethal challenge doses, and made a reduced anti-LVS antibody response (Yee, 1996). The relationship, if any, between these two observations remains to be explored further. Dramatic polyclonal expansion of V(9/V δ 2 T cells in the peripheral blood cells of tularemia patients within 7–10 days after apparent infection has recently been observed (Sumida, 1992; Poquet, 1998). This was interpreted as suggesting that *Francisella* may possess a superantigen that stimulates a particular $\gamma\delta^+$ T cell receptor without regard to antigen specificity (Sumida, 1992), and evidence for a non-peptide phosphoantigen derived from virulent *Francisella* (but not LVS) has been presented (Poquet, 1999). This is of particular note since other studies using a comprehensive set of *Francisella* proteins to stimulate human PBLs have not detected such a molecule (Surcel, 1990).

Humans infected with wild-type *Francisella* exhibit a T cell-dependent delayed-type hypersensitivity response within about a week of infection (Buchanan, 1971), a response that has been exploited to develop a skin test for diagnosis. Early responses of cells of the innate human

immune system, and corresponding cytokine production, to primary infection with wild-type *Francisella* or to vaccination with LVS have not been comprehensively studied. Primary T cell responses in human volunteers vaccinated with LVS have been described. By days 10–14 after LVS vaccination, in vitro proliferative responses by PBLs to killed bacteria were detected, and by day 14 IL-2, IFN γ , and TNF α production (but not IL-4 production) was observed (Karttunen, 1991). Similarly, proliferative responses to killed bacteria by PBLs obtained from tularemia patients were demonstrated 2 weeks after appearance of symptoms; production of TNF α ; could be detected within 1 week, and IL-2 and IFN γ (but not IL-4) were found from 2 weeks onward (Surcel, 1991a). The T cell or monocyte contribution to either proliferation or cytokine production was not specifically determined, however.

The nature of the LVS antigens recognized by mouse T cells has not been completely studied. At least one lipoprotein, designated TUL4, stimulated proliferation of T cells from vaccinated people (Sjöstedt, 1989); further, TUL4 stimulated both proliferation and cytokine secretion in T cells from immune mice (Sjöstedt, 1992b), but this protein does not appear to be immunodominant. Similarly, the human T cell response to *Francisella* appears to be heterogeneous as well as long lived. Peripheral blood lymphocytes or purified T cells (in the presence of monocytes) from LVS-vaccinated people proliferated in vitro when incubated with heat-killed bacteria (Tärnvik, 1975; Tärnvik, 1978); this proliferative response was due primarily to recognition of a wide variety of proteins, at least some of which are outer membrane proteins (Sandström, 1987; Surcel, 1989; Surcel, 1990; Sjöstedt, 1992a). Subjects who recovered from natural tularemia infection between 2 weeks and 25 years earlier also had PBLs that proliferated in response to heat-killed bacteria (Koskela, 1980; Ericsson, 1994) and to a variety of bacterial proteins as well (Sjöstedt, 1990). The T cell responses to at least four of these proteins were observed in cells from both naturally infected subjects and LVS-vaccinated subjects, suggesting that antigenic proteins important in human responses to wild-type infection also are expressed by LVS; as with mice, however, no obvious immunodominant human antigen has been found. Upon antigen stimulation in vitro, T cells from either vaccinated or naturally infected individuals produced IL-2 and IFN and exhibited upregulated IL-2 receptor expression (Karttunen, 1987). The T cell clones established from PBLs of both naturally infected subjects and LVS-vaccinated subjects have been reported and were class II restricted, CD4⁺, and produced IL-2 and IFN, and provided

help for in vitro antibody production (Surcel, 1989; Sjöstedt, 1990; Surcel, 1990; Sjöstedt, 1992a). Although both *Francisella*-specific proliferative and Th1 cytokine production responses by the CD45RO⁺ (memory) / CD4⁺ T cell subset were readily demonstrated, responses from the CD8⁺ subset were detected as well (Sjöstedt, 1992a). T cells from LVS-immune mice also proliferated in response to heat-killed bacteria. As might be expected, the proliferative response was dependent on macrophages, and the interaction between macrophages and T cells was H-2 (and largely class II) restricted (Anthony, 1988). Although such observations suggest that CD4⁺ T cells might be especially important in immunity to *Francisella*, the observed ability of mice totally lacking CD4⁺ T cells to readily resolve both primary and secondary LVS infection must be remembered (Yee, 1996).

It has proven very difficult to stimulate strong protection against intracellular pathogens by immunization with killed bacteria, including in *Francisella* infection (Foshay, 1950; Claflin, 1972; Hambleton, 1974). Since the generation of a specific antibody response is very similar to both killed bacteria and live infection, it has been inferred that antibody is not sufficient for successful protection. Further, in experimental situations where little or no specific antibody is present, excellent protection can be demonstrated. Nonetheless, the antibody response to *Francisella* has been studied in some detail in both animals and humans because it has proven useful in diagnosis. In mice, IgM anti-LVS antibody responses were detected 5 days after infection, reached a peak by 2 weeks after infection, and slowly declined thereafter but persisted for more than 4 months (Rhinehart-Jones, 1994). The IgG anti-LVS antibody responses were detected 10 days after infection and peaked by about 1 month, and were maintained at a plateau level for at least 4 months. The overwhelming majority of the specific IgG response was of the IgG_{2a} subclass, as might be expected for an infection that results in production of high levels of IFN γ . Much of the anti-LVS response in both mice and humans appears to be directed against the LPS of the bacterium (Viljanen, 1983). Some limited protection could be transferred to naive mice with IgG anti-LVS antibodies, but the strength of this protection was quite small compared to that afforded by immunization with live bacteria, and no protection could be transferred with IgM anti-LVS antibodies (Rhinehart-Jones, 1994). Other studies indicated that anti-LVS antibodies affected the relative distribution of bacteria in organs but not overall mortality (Anthony, 1987). In contrast, CD4⁻ knockout mice infected with LVS produced only small amounts of IgM anti-LVS antibodies but were

able to survive a maximal secondary lethal challenge (Yee, 1996). Older literature demonstrated that serum from animals infected with wild-type *F. tularensis* was unable to transfer protection against wild-type challenge as well, and at best slightly extended the mean time to death (Allen, 1962; Thorpe, 1965). In addition, anti-*Francisella* antibodies appear to have little functional activity in that neither bacteriocidal action nor opsonization for uptake and subsequent killing by macrophages or PMNs has been readily demonstrated in vitro (Löfgren, 1983; Sandström, 1988; Rhinehart-Jones, 1994). Taken together, these results indicate that anti-LVS antibodies are neither necessary nor sufficient for optimal secondary immunity to *Francisella*.

In humans naturally infected with *F. tularensis*, specific IgM, IgG, and IgA serum antibodies appear almost simultaneously about 6–10 days after the onset of symptoms, or about 2 weeks after infection. All isotypes peak about 1 to 2 months after infection and can still be detected up to 11 years later (Koskela, 1985). However, most subjects who recovered from natural infection did not have significant amounts of specific anti-*Francisella* antibodies in their serum 25 years later (Ericsson, 1994). Similarly, in humans vaccinated with LVS, specific IgM, IgA, and IgG antibodies were detected in serum about 2 weeks after vaccination and persisted for at least 1.5 years (Koskela, 1982). There is no apparent correlation between levels of serum antibodies in human sera and protection against subsequent tularemia infection. For example, two vaccinated laboratory workers known to have high titers of agglutinating antibodies at the time of infection nonetheless suffered severe tularemia following a laboratory exposure (Overholt, 1961).

The extent of disease and its effect on military operations spurred interest in development of a tularemia vaccine in the former Soviet Union in the 1940s; in the West, efforts at vaccination began with development of killed vaccines (Foshay, 1950), but it soon became clear that killed vaccine or antigen preparations were relatively ineffective in disease prevention. Scientists at the Gamaleia Institute in the former Soviet Union apparently used several different methods to develop attenuated strains, starting with clinical isolates that were not well documented but were probably *F. tularensis* type B. The preferred method was repeated passage on artificial media, and in the mid-1940s, an attenuated strain (designated “strain 15”) with greatly reduced virulence for guinea pigs and substantially reduced virulence for mice, was derived (Tigertt, 1962). After initial promising results with human use, mass vaccination of several million people were undertaken between 1946 and 1955 (Sandström, 1994). In the course of manufacturing various

lots of vaccine, however, an inverse correlation between virulence in animals and immunogenicity in people was noted. New lots that failed to kill some mice but still killed all guinea pigs (failure to kill guinea pigs was considered indicative of successful attenuation) also were thought to be less effective as vaccines. By about 1955 the original strain 15 apparently had become so attenuated that it no longer retained the necessary "residual virulence," and thus efforts to derive new strains were undertaken. Strain 15, itself, was "restored" by passage through animals to approximate its original virulence profile, and a new strain (called 155), with a phenotype in animals similar to the original strain 15, was derived through passage on artificial media. By 1960, after several decades of mass vaccination with various attenuated strains, it was stated that only a few hundred cases of tularemia occurred annually (Tigertt, 1962). More recent data are not readily available.

In 1956, a "medical mission" of United States Army doctors to the Soviet Union brought back an ampoule of tularemia vaccine from the Gamaleia Institute to the military research institute at Ft. Detrick, MD; the label on this vial suggests it was a mixture of strain 155 and the "restored" strain 15. At Ft. Detrick, culture of isolated colonies revealed that, as had previously been described in the Soviet literature, two colony morphologies could be discerned on agar plates under oblique light. Colonies of the so-called "blue variant" were small, opaque, and raised, while those of the "gray variant" were larger, transparent, and flat. Efforts to separate the two variants were not entirely successful, but organisms derived from liquid cultures of mostly blue colonies apparently were more virulent and more immunogenic for both guinea pigs and mice than were organisms derived from cultures of mostly gray colonies (Eigelsbach, 1961). For reasons that are not obvious, organisms derived from isolated blue colonies were then serially passaged through mice five times; each time, virulence apparently increased, and at the last passage the bacteria were isolated from the blood of moribund animals. The final isolate was designated LVS, for Live Vaccine Strain (Eigelsbach, 1961).

The LVS is thus significantly more virulent for mice than strains used in Soviet mass vaccination programs, and, in fact, appears to have essentially full virulence for modern inbred strains of laboratory mice: a single bacterium inoculated intraperitoneally or intravenously is generally lethal for BALB/c mice. In mice as well as in guinea pigs, LVS causes a fulminant disease that is histopathologically quite similar to human tularemia. Thus, study of LVS infection of mice has been widely used as a model for study of virulent human tularemia, and in fact, as a gen-

eralized model intracellular infection (Tärnvik, 1992; Anthony, 1987; Fortier, 1991; Yee, 1996). Regrettably, because genetic systems for *F. tularensis* are in the early stages of development, the genetic basis of attenuation of LVS remains uncharacterized; thus, it is not yet possible to evaluate the relationship between LVS and fully virulent *F. tularensis* type B. However, sequencing of the genome of the virulent *F. tularensis* strain Schu 4 is near completion, and thus genomic information may soon be brought to bear on the question of the genetic basis of attenuation of LVS.

The acceptability and success in humans of LVS as a vaccine, which is not licensed for use in the United States, are uncertain. The LVS has had limited distribution in the United States as an Investigational New Drug (IND) product to qualified collaborators by the US Army Medical Research Institute in Infectious Diseases (USAMRIID) at Ft. Detrick, for use in research, vaccination of laboratory workers, and other "at risk" populations. A number of somewhat limited studies have been offered in support of its efficacy against either Type A or Type B tularemia. Remarkably, aerosol challenge studies in human volunteers were performed in the late 1950s, in which volunteers were given LVS by scarification and subsequently challenged by inhalation with virulent Schu S4 strain, the clinical Type A isolate (McCrumb, 1961). Results in this limited population suggested that some protection against development of symptoms was afforded, at least at lower challenge doses; similar observations in a monkey model also have been published (Eigelsbach, 1962). An analysis of laboratory-acquired cases at USAMRIID among civilian workers before and after LVS was routinely used for vaccination was interpreted to indicate that LVS prevented typhoidal tularemia, including pneumonic tularemia, fairly well and at least ameliorated symptoms of ulceroglandular tularemia (Burke, 1977). However, the time periods studied coincided with development and introduction of considerable improvements in containment of biologicals and safe handling procedures, weakening the conclusions of this analysis. Disease in the United States is now so rare and sporadic that designing appropriate field trials of vaccine candidates is not feasible. Further, safety studies to date indicate that LVS has significant reactogenicity (as might be expected for a strain that was derived, in part, by deliberately increasing its virulence for animals), and its potential to revert to virulence for humans cannot be adequately assessed. Newer lots of LVS have varied in their relative proportions of blue and gray colonies (from 1 to 20% gray), with unknown effects on overall efficacy (Waag, 1995). Appreciation of the appearance of

blue and gray colonies as a consequence of the capacity of *F. tularensis* LVS to undergo phase variation of LPS expression (Cowley, 1996) also raises questions about difficulties in consistency of manufacture using this strain. Other efforts to develop alternate vaccine candidates may be spurred by the availability of sequence information and recent improvements in genetic systems for manipulating the *F. tularensis* genome.

Ecophysiology of the Genus *Shewanella*

KENNETH H. NEALSON AND JAMES SCOTT

Introduction

The genus *Shewanella* is comprised of more than 20 species inhabiting a wide range of environments including spoiled food, oil field wastes, redox interfaces in marine and freshwater, cold waters and sediments of the deep sea, and mesophilic ones all around the planet. Much of the recent interest in the shewanellae stems from their almost notorious abilities in the area of anaerobic respiration; these bacteria appear to be able to use nearly any electron acceptor more electronegative than sulfate, including oxygen. However, the genus is much more than just a group of respiratory specialists, as will be discussed here.

As with many contemporary genera, the *Shewanella* have experienced a rocky road to their present status, as evidenced by the species *S. putrefaciens*. Originally isolated as an active agent in food spoilage (Derby and Hammer, 1932), this organism was first called “*Achromobacter putrefaciens*,” then *Pseudomonas putrefaciens* (Shewan et al., 1960), *Alteromonas putrefaciens* (Lee et al., 1977), and finally *Shewanella putrefaciens* (MacDonell and Colwell, 1985). One notable strain of *S. putrefaciens* called “MR-1” was isolated from Oneida Lake, New York, as a metal reducer, and after genome sequencing was begun, the epithet was changed to *S. oneidensis* on the basis of molecular data, including 16S rRNA sequence analyses, DNA gyrase sequence analyses, lipid analyses, and DNA/DNA hybridization (Venkateswaran et al., 1999).

Several *Shewanella* species have been found in Antarctic Continental shelf sediments (Bozal et al., 2002) as well as in sea-ice microbial communities (adapted to grow at temperatures below 4°C) isolated from McMurdo, Antarctica (Brown and Bowman, 2001). Some of these (like *S. livingstonensis*; Bozal et al., 2002) are cultivated strains, while others (such as McMurdo.10) are as yet uncultivated and exemplify psychrophilic Antarctic strains identified only via sequence analysis of 16S rDNA (Fig. 1). Some of the psychrophilic strains are also tolerant of high

pressures, i.e., piezotolerant (Kato and Nogi, 2001). To date, only a few genera are known to have piezophilic members, and the regulation and growth under high pressure conditions of two notable species *S. benthica* (Kato et al., 1998) and *S. violacea* (Nogi et al., 1998; Nakasone et al., 1999) are under intensive study (Tamegai et al., 1998; Yamada et al., 2000).

Finally, the carbon source of many *Shewanella* strains is quite restricted, mainly fermentation end products such as lactate, some amino acids, formate, and hydrogen. Members of this group thus live a syntrophic lifestyle, in rich environments, and in association with fermentative communities that supply them the needed nutrients.

The placement of the various species within the genus *Shewanella* has largely been via the similarity of 16S rRNA sequences (Fig. 1), and while the organisms are indeed taxonomically linked by this criterion, they represent a wide range of physiological types, inhabiting many different niches (Table 1). This issue will arise several times, as it appears that the linkage on the basis of 16S rRNA may have the effect of removing virtually every physiological trait and ecological characteristic used as identifiers of the genus.

Physiology and Habitats of the Shewanellae

The type strain of *Shewanella putrefaciens* is a Gram-negative γ -Proteobacteria that is motile by a single polar flagellum. It produces hydrogen sulfide when grown anaerobically on thiosulfate or polysulfide, is incapable of glycolysis and fermentation, grows on lactate, pyruvate, formate, and a few amino acids, and is capable of respiratory growth on oxygen as well as a variety of different electron acceptors, including nitrate, thiosulfate, elemental sulfur, iron oxide, and manganese oxide. This combination of traits is nearly diagnostic for many (but not all) of the shewanellae. However as more *Shewanella* species are characterized and grouped according to their 16S rDNA sequence similarities, it has become increasingly clear that these traits do not

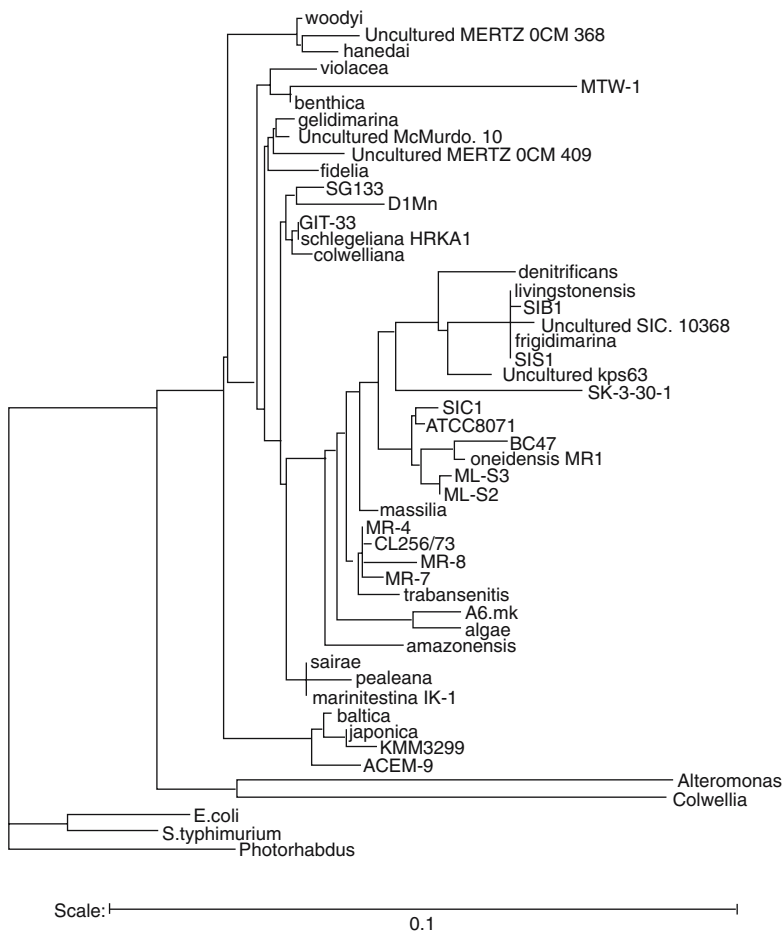

Fig. 1. Phylogenetic tree of about 40 *Shewanella* was constructed on the basis of 16S rRNA DNA sequences from both cultured clones and polymerase chain reaction (PCR) amplicons from a wide range of environments. The sequences were obtained from [the National Center for Biotechnology and Information website]. The tree was constructed using the online alignment, matrix calculation and tree building tools of the (Ribosomal Database Project (RDP-II); <http://rdp.cme.msu.edu>) at Michigan State University in East Lansing, Michigan (Maidak et al., 2001). All sequences are in the γ -Proteobacteria, and are linked to *Alteromonas* and *Colwellia* on one side, and *Escherichia*, *Salmonella* and *Photobacterium* on the other. The tree was constructed from 400 nucleotide positions using the Phylip program. The maximum likelihood distance matrix was utilized with *Photobacterium* being used as the outgroup for construction of the tree.

define all the members of the genus. Thus, to elucidate the ecophysiological features (if any) that may be common to all, the physiological traits that distinguish various *Shewanella* species are discussed before environments where they are common and abundant.

Carbon and Energy Utilization

The carbon utilization of many isolates of *Shewanella* has been screened, and in general, ability to use complex carbon sources is absent. There is a strong preference for lactate as a carbon source, and an apparent inability to utilize many complex carbon sources under anaerobic conditions (Myers and Nealson, 1988; Venkateswaran et al., 1999). Overall, strains prefer lactate, pyruvate, or simple amino acids (Ringo et al., 1984), rarely utilize glucose, and are non-fermentative. By contrast, some of the recent psychrophilic isolates in the *frigidimarina* and other groups not only utilize glucose and other sugars, but are reported to ferment them as well (Bowman et al., 1997; Venkateswaran et al., 1999; Reid and Gordon, 1999; Kato and Nogi, 2001). Given that their metabolism is based on

the respiration of simple carbon sources (lactate, pyruvate, formate, and some amino acids) and/or hydrogen, it is reasonable that, like many sulfate reducers, the shewanellae should be syntrophic partners of fermentative microbes, driving anaerobic metabolism forward via the removal of fermentation end products (Fig. 2). In addition, under anaerobic conditions, when grown on lactate, the shewanellae release CO_2 and acetate as end products. Again, the excretion of acetate is similar to that seen for many sulfate reducers, and suggestive of a lifestyle involving syntrophic partners capable of acetate utilization. Unlike the sulfate reducers, however, the shewanellae are capable of growth on a wide range of electron acceptors, including oxygen, are almost uniformly capable of the reduction of elemental sulfur, and are incapable of growth on sulfate as an electron acceptor.

Some detailed studies of carbon metabolism provide insights into the metabolism of the shewanellae, and the following statements paint a general picture of the group. Under aerobic conditions, *S. oneidensis* MR-1 utilizes a standard tricarboxylic acid (TCA) cycle for carbon metabolism, while under anaerobic conditions, other

Fig. 2. Syntrophic opportunities for the shewanellae. Under anaerobic conditions, the shewanellae utilize many of the products produced by fermentative communities, enhancing the breakdown processes. If growing on lactate, they excrete copious amounts of acetate on one hand, and reduced electron acceptors on the other. The acetate can be utilized by many anaerobic organisms, especially methanogens, while both the acetate and the reduced inorganics can be utilized by aerobic organisms.

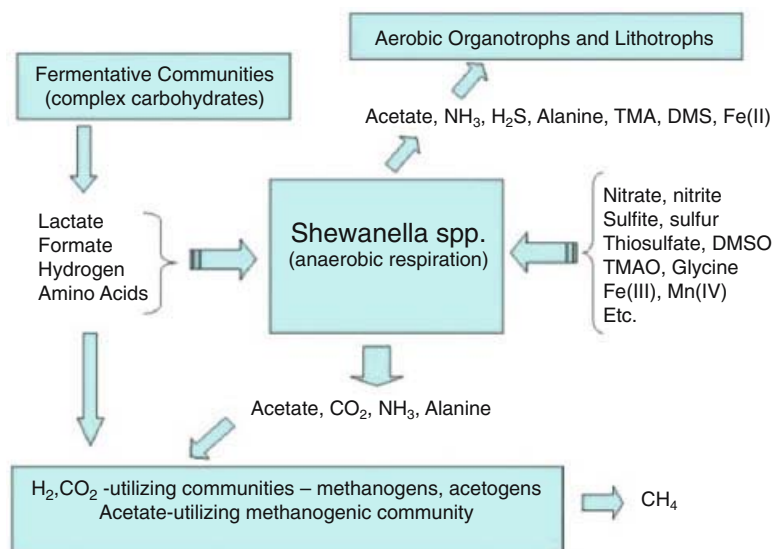

Table 1. Molar growth yields and products excreted by *S. putrefaciens* growing anaerobically with TMAO as electron acceptor.

Substrate	Growth yield ^a	Generation time (h)	CO ₂ ^b	Acetate ^b	Alanine ^b	NH ₃ ^b	%C recovered
Serine	17.5	12	2.8	0.0	0.11	0.9	104
Cysteine	17.5	12	2.7	0.0	0.10	1.1	98
Lactate	11.5	7	2.0	0.42	0.06	0.3	100
Formate	5.0	13	nd	0.0	0.0	0.2	nd

Abbreviations: TMAO, trimethylamine oxide; and n.d., no data.

^aMolar growth yield as µg dry weight/µmole of substrate oxidized.

^bProduct excreted is expressed µmol/µmole of substrate oxidized.

Data from Ringo et al. (1984).

pathways are used (Scott and Nealson, 1994). Under anoxic conditions, during growth on lactate, acetate accumulates in the growth medium, probably via the acetyl-phosphate pathway, and is not further utilized. These results are in accord with the work of Ringo et al. (1984), who showed that with lactate, the incomplete oxidation pattern of carbon to CO₂ observed under anoxic conditions was inconsistent with the operation of a complete TCA cycle. It is also consistent with isotopic measurements that show a difference in carbon fractionation between aerobically and anaerobically grown cells (Teece et al., 1999).

Since growth is fastest with lactate as the carbon source, lactate is often the preferred substrate for anaerobic studies of the shewanellae. Reports of the growth on lactate vary, with some reports of anaerobic growth showing a 1 : 1 stoichiometry of lactate conversion to acetate and CO₂ (Lovley et al., 1989; Caccavo et al., 1992), and an earlier report that about 40% of the lactate (on a molar basis) was excreted as acetate (Ringo et al., 1984) by *S. putrefaciens* NCMB1735. The latter authors also noted that

growth on amino acids such as serine or cysteine resulted in higher molar growth yields, with no excretion of organic acids (see Table 1). Growth on formate resulted in low molar growth yields and no excretion of organic acids.

Shewanella putrefaciens (Lovley et al., 1989) and *S. algae* (Caccavo et al., 1992) can use H₂ as an energy source, and the ability of these species to remove hydrogen is such that they can out-compete sulfate reducers for hydrogen. On the basis of studies on the binding properties of uptake hydrogenases in *Shewanella putrefaciens*, at least in soil systems, Klüber and Conrad (1993) concluded that *S. putrefaciens* does not play an important role in hydrogen oxidation in that environment.

In another study of a *Shewanella* isolate (almost certainly not *S. putrefaciens*, on the basis of carbon source utilization), glucose was used as the carbon source, and nitrate as the electron acceptor (Samuelsson, 1985). While the organism showed no growth on glucose alone, it was capable of nitrate reduction, with conversion to either nitrogen or ammonia, depending on the

redox status of the medium. Such studies demonstrate the complexities of this group of organisms, and the dangers of generalization.

Electron Acceptor Utilization

Many bacteria are somewhat versatile with regard to respiration, but few exhibit the range of activity seen in the shewanellae. The list is probably not complete, but so far, shewanellae have been shown to reduce more than 20 different electron acceptors (Table 2). This versatility is reflected in the number of cytochromes, especially *c*-type cytochromes, and in the number of cytochrome genes seen in the sequenced genome of *S. oneidensis* MR-1; [The Institute of Genomic Research [TIGR] Web site]. So far, over 40 *c*-type cytochromes are known, a great many in comparison to other bacteria of similar genome size. While the number is large,

few duplicates seem to exist, and this anomaly should be addressable via mutagenesis experiments, now underway in many different laboratories.

Iron and Manganese Oxide Reduction

With regard to electron acceptor utilization, the shewanellae are known have a series of abilities not common to other aerobic bacteria: namely, the dissimilatory reduction of solid iron and manganese oxides, and polysulfide (see below). We say this with some caution, inasmuch as the dissimilatory reduction of metals was shown many years after the deposition of the type strain of this organism in the American Type Culture Collection, and the same could easily be true of other groups of bacteria already in "captivity." The ability to reduce iron was reported many years ago, even for some of the strains of *S. putre-*

^aThe products of reduction are the primary products. For the metals, a variety of products are formed, depending on environmental conditions.

^bAs near as possible, these represent the first reports of specific electron acceptor utilization, and other useful references. The list is not complete.

faciens (Obuekwe et al., 1981; Obuekwe and Westlake, 1982; Semple and Westlake, 1987), but the unequivocal evidence that metal reduction was coupled to cellular metabolism and growth in the shewanellae was not reported until the late 1980s (DiChristina et al., 1988; Myers and Nealson, 1988). Since then, many metal reducers in a wide range of bacteria and archaea have been reported to be dissimilatory metal-reducing bacteria (DMRB). Now, reduction of a wide range of iron oxides as well as iron rich clays has been shown (Table 2).

The ability to reduce metal oxides is one that was doubted for many years because of the fact that most of the oxidized metals available in abundance in nature are solids (iron and manganese oxides form a range of insoluble forms, and virtually no soluble forms with the exception of organic ligands of Mn[III] and Fe[III]). The existence of the solid oxides within a metal's cycle provides an interesting twist for two reasons. First, in stratified water bodies like meromictic lakes or fjords, because the oxidized solid forms of iron and manganese sink, the cycling of these metals is in effect an oxidant pump, delivering oxidizing equivalents to the deeper waters. It is essentially a gravity-driven redox cycle (Fig. 3). In sedimentary environments, on the other hand, the layers of oxidized metals are fixed into the soils or sediments, and if not completely reduced by the next cycle of nutrients (usually

on a yearly cycle in temperate zones), they can leave a layer of oxidized iron and/or manganese in the sediments—a record of previous microbial metal cycling in the soils.

One of the predictable outcomes of interacting with solid surfaces as oxidants is that the reaction rates can be a function of surface area rather than cell number. Burdige et al. (1992) studied reduction of a series of manganese oxides by various shewanellae, and have shown that surface area of the oxides is of great importance with regard to predicting rates of reaction. In fact, some “aged” oxides like pyrolusite are virtually unavailable to the shewanellae as electron acceptors, owing likely to a combination of low surface area and high crystallinity (Burdige et al., 1992). Similar conclusions have been reached with studies of iron oxides by a number of different workers (Roden and Zachara, 1996b; Urrutia et al., 1998), concluding that surface area and crystallinity are the major factors that determine the rates of reduction. Such information is of more than idle interest to those wishing to study these processes in that positive results are difficult to obtain if highly crystalline oxides of low surface area are used for experiments, especially for initial enrichments.

Another important part of the metal cycle is the ability of metal oxides to act as natural ligands for other metals. This is particularly true for manganese oxides (notorious for their ability

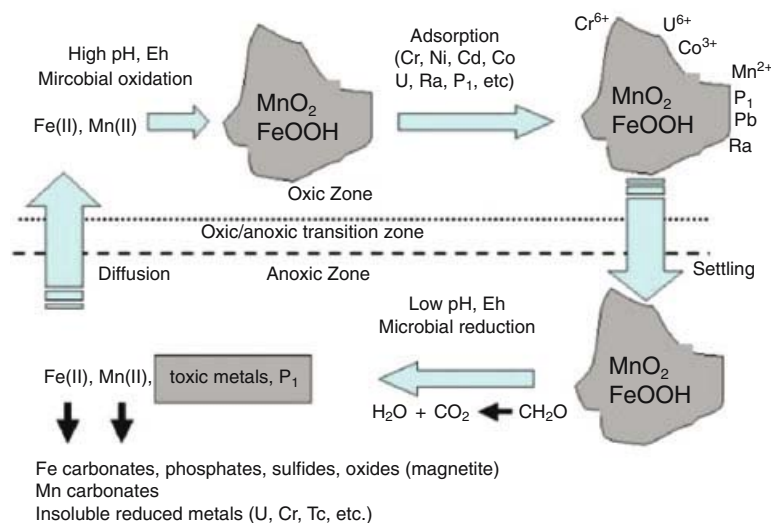

Fig. 3. The major processes occurring during the biogeochemical cycling of iron and manganese oxides across the oxic/anoxic boundary. Under conditions of high Eh and pH, iron and manganese are oxidized, and form hydrous metal oxides and oxyhydroxides. These fresh oxides are strong ligands for a variety of transition metals and actinides, as well as some heavy metals, and phosphorous, so that the insoluble oxides act as sinks for these other metals, transporting them to sedimentary environments via precipitation. In the anoxic zone, reduction occurs, either spontaneously via Eh/pH effects, or via microbial catalysis. This results in the release of the bound metals as well as Fe(II) and Mn(II), and the recycling of iron and manganese via diffusion to the oxic zone. In addition, secondary metals can be formed, depending on the chemistry of the anoxic environment in which the reduction is occurring.

to bind cations of all kinds) and for iron oxides, which strongly bind phosphate. Reduction of these oxides can then result in the release of a number of other metals into solution. Phosphate can be beneficial, and in oxic soils or marine environments, the availability of iron-reducing bacteria as symbionts may well be an important strategy in avoiding phosphorous limitation (Fig. 3). A recent proposal suggests that there have been major times in the Earth's history when productivity of the oceans was limited by phosphate, and that the relief of this limitation was achieved via iron reduction (Bjerrum and Canfield, 2002). In other cases of metal reduction, potentially toxic metals may be released, causing potential problems, or at least allowing them to diffuse to other sites. An example of such a case is shown in Fig. 4, where the cycle of uranium (U) in the Mississippi Delta is shown to be strongly regulated by the reduction of Mn oxides (Nealson et al., 2002).

Fig. 4. Release of uranium during metal reduction. This profile plotted from data obtained during a cruise to the Amazon Delta region (Nealson et al., 2002), shows the porewater profiles of soluble iron, manganese and uranium. As seen, the uranium, which is in its soluble, oxidized (U[VI]) state, tracks almost perfectly the profile seen for Mn. This is because as the sedimentary Mn oxides are reduced by dissimilatory metal reducing bacteria (DMRB), the uranium, which is loosely bound to the Mn oxides is released into the sediments. In contrast, there appears to be no relationship between the profile of soluble iron and uranium.

The enzymatic mechanism(s) leading to metal reduction is not yet fully elucidated (Newman, 2001), and will not be reviewed here. Suffice it to say that many advances have been made, including investigations of many enzymes, genes coding for these enzymes, regulation of metal reduction, and the possibility that extracellular electron shuttles are utilized for metal reduction. From the work of several laboratories, some of the enzymes involved in metal reduction are clearly located on the outer cell wall of the shewanellae (Myers and Myers, 1992b; Myers and Myers, 1993a; Myers and Myers, 1998; Myers and Myers, 2001; Beliaev and Saffarini, 1998; Field et al., 2000; Gordon et al., 2000; Beliaev et al., 2001; DiChristina et al., 2002). Given the early reports that the reduction of solid metal oxides required cell contact with the oxides, and the more recent reports that reduction of iron requires cell adhesion (Caccavo, 1999; Das and Caccavo, 2000; Das and Caccavo, 2001), the location of such enzymes is reasonable, although the mechanism(s) whereby energy is conserved during reduction will of necessity be different from the more standard redox systems of other bacteria.

The role of quinones is not entirely elucidated, but through the work of several laboratories, it is clear that under anaerobic conditions, menaquinones are synthesized and play a major role in metal reduction. Mutants deficient in quinone production are defective in metal reduction as well as the reduction of several other substrates (Myers and Myers, 1993b; Saffarini et al., 2002). The shewanellae, along with a few other species of primarily aerobic bacteria produce methylmenaquinones (MMKs; Venkateswaran et al., 1999), and the presence of specific MMKs has been proposed as a taxonomic trait of these groups (Akagawa-Matsushita et al., 1992). Interest in quinone physiology has recently increased with the reports of Newman and Kolter (2000) and Hernandez and Newman (2001) that surface contact is not always necessary for metal reduction. Instead, they postulate that external "electron shuttles" in the form of quinones are utilized for metal reduction. These workers have shown that it is possible to isolate *S. oneidensis* mutants that cannot reduce solid iron unless supplied with quinones of the proper type. The resolution of this issue has important implications for the ecology of the metal-reducing shewanellae, as their interaction with surfaces may be a significant part of their strategy for survival and success. If surface interaction is unnecessary, or necessary only at certain times or in certain niches, these details of metal reduction will need to be determined to understand the ecophysiology of this group.

Environmental Effects of Fe and Mn Oxide Reduction

In carbon-rich sediments, metal reduction can be a major process and account for much of the carbon cycling. As shown in Table 3, a number of environments are now characterized where from 20% to virtually all of the carbon oxidized can be accounted for by metal reduction (see Thamdrup, 2000a for a comprehensive review). In general, metal cycling can play a major role in carbon-rich aquatic sediments, and even in marine systems, where it is usually assumed that sulfate reduction dominates. This view of the role of metals in the overall carbon cycling of sedimentary environments constitutes a major change in thinking, which has taken place over the last decade. Prior to this, the solid metals were considered to be rather inactive, and their role in carbon mineralization at the most was considered to be stoichiometric. It is now clear from work like that cited in Table 3 that metals may turn over many times before being buried, and can be a dynamic component of many sedimentary environments.

In addition to the cycling of organic carbon, metal reduction has physical effects—solid metal oxides are solubilized and allowed to diffuse away so that the very texture of an environment is changed. A laboratory example (see Fig. 5) is a culture of *S. oneidensis* solubilizing the solid MnO_2 . The complete solubilization of metal oxide occurs in a few days, and in systems where oxygen is available, Mn reoxidation can occur rapidly, resulting in a cyclic oxidation similar to that shown in Fig. 2. Another physical effect is that seen with smectite clays, which upon iron reduction can change their swelling capacity, charge, and other physical properties resulting in major changes to the soil environment (Kostka et al., 1996; Kostka et al., 1999b; Kostka et al., 1999c).

Finally, as noted in Fig. 3, metal reducing bacteria interact via the formation of new minerals

upon reduction of iron and/or Mn oxides. When iron oxides are reduced, the fate of the Fe(II) is specified by the environment as much or more than by the bacterium. Thus, one can alter the iron to form siderite (iron carbonate), magnetite (a mixed phase iron oxide), pyrite or other iron sulfides, or vivianite (iron phosphate), and perhaps many other products, simply by growing the cells in media with different buffer systems (Nealson and Saffarini, 1995a; Roden and Zachara, 1996b; Urrutia et al., 1998; Urrutia et al., 1999; Bjerrum and Canfield, 2002). The introduction of Fe(II) or Mn(II) and reformation into new mineral forms is of course potentially very important with regard to the ecosystem dynamics.

Reduction of Sulfur Compounds

The shewanellae are unusual, perhaps unique, as aerobic bacteria, in their ability to grow at the expense of elemental sulfur (in the form of polysulfide; Moser and Nealson, 1996). They produce hydrogen sulfide (H_2S) from thiosulfate, sulfite, or polysulfide, and are remarkably resistant to H_2S (Perry et al., 1993). As such, they are as “comfortable” at interfaces with sulfate-reducing bacteria as they are with aerobic heterotrophs, and span a very wide range of ecological niches in layered communities like those of the Black Sea (Nealson et al., 1991). Very little work has been done with the sulfur-reducing systems in the shewanellae, and sulfur reduction (especially in marine systems) may be one of the potentially important roles of such organisms.

Reduction of Nitrogen Compounds

The shewanellae are capable of reduction of nitrate to nitrite, nitrous oxide, ammonium, or dinitrogen, depending on conditions (Samuelsson, 1985). Brettar and Höfle (1993) identified *S. putrefaciens* (now named “*S. baltica*”; Ziemke et al., 1998) as the major organism present and

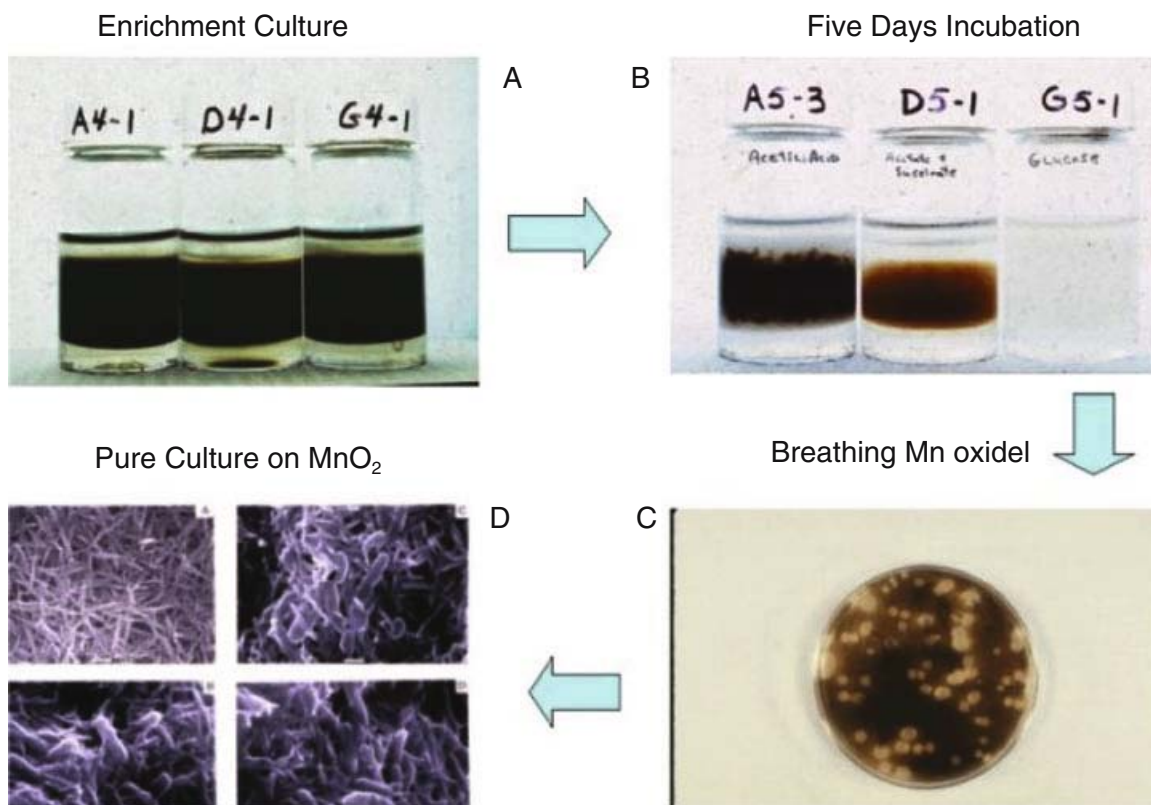

Fig. 5. *Shewanella oneidensis* and manganese reduction. A. Enrichment cultures set up for isolation of dissimilatory metal-reducing bacteria (DMRB)—soft agar vials or tubes containing MnO_2 as the only electron acceptor. Enrichments are covered with a layer of mineral oil to keep them anaerobic, and contain one or more carbon sources. B. Enrichments after several days of growth. Poisoned or uninoculated samples show no change, while those with inocula show variable results depending on the carbon sources added. Here acetate, acetate plus succinate, and glucose utilized as carbon sources are seen. The glucose has resulted in metal reduction owing to acid production. C. Enrichments on lactate-media plates are incubated with an overlay of MnO_2 -containing top agar. Clearings in the top agar layer are due to reduction of the MnO_2 by dissimilatory metal-reducing bacteria (DMRB). D. Scanning electron microscopic views of pure DMRB (*S. oneidensis*) cultures growing on MnOOH surfaces. Upper left = uninoculated surface, Others = bacteria attached to surface.

responsible for organic carbon cycling and nitrous oxide production at the oxic/anoxic interface in the Central Baltic Sea, and proposed that it was a major factor in the carbon/nitrogen cycle in this marine environment. As with the sulfur compounds, much work is yet to be done on the physiology of nitrogen oxide reduction by the shewanellae, but the abundance of these organisms at nitrate-rich interfaces in the Black Sea (Nealson et al., 1991) and other marine environments, as well as the above-cited work leads to the conclusion that shewanellae will have major environmental impacts on the nitrogen cycle and its coupling to the oxidation and cycling of organic carbon.

Reduction of Other Inorganic Electron Acceptors

As shown in Table 2, the shewanellae are capable of reducing a seemingly endless array of electron

acceptors down to the level of sulfate, but not including either sulfate or CO_2 . This includes oxidized forms of chromium, selenium, arsenic, uranium and technetium (Fredrickson and Gorby, 1996; Fredrickson et al., 2000; Wade and DiChristina, 2000; Wildung et al., 2000). The ecological importance of these reactions is unknown, but they all have potential bioremediation uses, as reduction of these toxic metals almost always alters their solubility.

Types of Habitats

Considering the above traits, the kinds of niches where shewanellae might be expected to be found include environments: 1) that are energy rich in which fermentation is occurring and energy is continuously being deposited via sedimentation; 2) where the redox conditions might change rapidly and shift the dominance of electron acceptors, including between oxic and

anoxic states; and 3) in which other partners are present to remove the acetate produced via anaerobic respiration. These general notions fit well with the recorded isolations of shewanellae from a wide variety of mostly energy-rich niches appropriate for multispecies anaerobic metabolism, and many of which are subject to periodic redox changes.

To some extent, the ability to use the products of other anaerobes and aerobes, and a wide variety of different electron acceptors, and the ability to sense and move towards electron acceptors, are all traits that make the shewanellae ideal gradient organisms (microbes not only tolerant of, but well suited to the “gradient lifestyle”) and would appear to be best adapted to syntrophic coexistence with other bacteria. Figure 6 is a schematic showing where the shewanellae have been found; some of these niches will be discussed in detail below. Of particular note is the expected (and observed) ability of the shewanellae to utilize oxygen, and thus not only tolerate rapid changes in redox status of the environment, but also thrive in them.

REDOX-RELATED HABITATS Considering the above, it is reasonable to expect that the redox interfaces, which exist nearly everywhere that biomass is produced and cycled, in the habitats occupied by the shewanellae are truly cosmopolitan, and include a wide variety of freshwater and marine niches, especially energy-rich and dynamic environments. Particularly in marine stratified communities, these versatile bacteria comprise major parts of the populations at

redox interfaces (Brettar and Höfle, 1993; Ziemke et al., 1997; Ziemke et al., 1998). For example, in the Black Sea, in which redox strata occur at intervals of many meters, viable counts of bacteria revealed shewanellae accumulated at anaerobic interfaces, and were below limits of detection in the intervening depths (Nealson et al., 1991). Similarly, Höfle and Brettar (1996) have reported the abundance of shewanellae at redox interfaces in the stratified water column of the North Sea, consequently labeling them with the very appropriate epithet “interface organisms.”

As environments become more oligotrophic, the occurrence and abundance of shewanellae tends to decline. For example, shewanellae are typically absent in low energy groundwater or vadose zone environments with constant conditions and low nutrient flow. Studies of North American lakes have supported this view (DiChristina and DeLong, 1993; MacGregor et al., 1997; Stein et al., 2001). In Green Bay or Oneida Lake sediments where sediment deposition rates are high, shewanellae are abundant. However, as one moves to environments with successively lower fluxes of organic carbon, e.g., to deeper parts of Green Bay and then to Lake Michigan, the shewanellae disappear and are replaced by other metal-reducing microbes (predominantly bacilli; C. Aguilar and K.H. Nealson, unpublished observation).

PATHOGENIC HABITATS Several different shewanellae have been implicated as opportunist pathogens of humans (Khashe and Jauda, 1988; Kim et al., 1989; Nozue et al., 1992; Dominguez et al., 1996; Holt et al., 1997; Iwata et al., 1999), and extensive work by Gram and colleagues (Gram et al., 1999; Vogel et al., 2000) has shown that the clinical isolates are virtually identical to those seen in environmental samples. The predominant organism capable of human infection is *S. algae*, which is also a remarkably versatile redox-active organism isolated from a variety of marine environments. This species, implicated in a case of human septicemia in Japan (Iwata et al., 1999), may well possess characteristics making it particularly suited as a human secondary or opportunistic pathogen. To this end, the shewanellae have been shown to produce only hydroxamate-type siderophores (Gram, 1994), one of which has been structurally characterized and designated as “putrebactin” (Ledyard and Butler, 1997). The siderophores of *S. algae* have not been characterized, but a slight difference in structure or regulation from that of *S. putrefaciens* could easily account for the apparently more virulent nature of this species. Only one isolate has been implicated in symbiosis with eukaryotic organisms: *S. pealeana* (Leonardo et

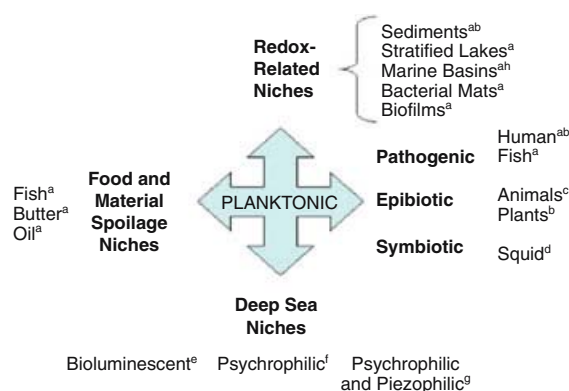

Fig. 6. The major niches of the shewanellae. As with many aquatic microbes, the niche often sampled is planktonic, but the niches are diverse. Superscripts have been added to indicate the major groups of the shewanellae found in each niche subdivision. These are a = *S. putrefaciens*, *S. oneidensis*; b = *S. algae*; c = *S. sairae*, *S. schlegeliana*, *S. marinintestina* ??; d = *S. pealeana*; e = *S. woodyi*, *S. hanedai*; f = *S. frigidimarina*, *S. gelidimarina*; g = *S. benthica*, *S. violaceae*; h = *S. baltica*; i = ??; j = *S. schlegi*, etc.

al., 1997), which was isolated from the nidamental gland of a marine squid. Several others, however, have been isolated as epibionts from both plant and animal materials (see below).

FOOD SPOILAGE HABITATS *Shewanella* species as a food spoilage organism was first reported by Derby and Hammer (1931), and the number of such reports has continued to grow since then. The shewanellae become dominant organisms on stored marine fish materials, and are probably one of the major organisms responsible for odor production via both trimethylamine oxide (TMAO) reduction to trimethylamine, and production of hydrogen sulfide (Levin, 1968; Gram et al., 1987; Gram et al., 1990; Jorgensen and Huss, 1989; Stenstrom and Molin, 1990; Subasinghe and Shariff, 1992; Gram, 1993). It seems likely that the rich nature of the food environment provides the type of habitat needed for the shewanellae, and the abundant TMAO (and sulfur compounds) in marine fish may make these habitats ideal for the shewanellae. Of particular interest are the species that can grow well near 0°C, such as *S. frigidimarina* and *S. gelidimarina* (Fig. 1), and their potential role in food quality degradation. Many of these species are capable of a much wider range of carbon metabolism than that normally seen in the mesophilic shewanellae (Bowman et al., 1997; Bowman et al., 2000).

DEEP SEA, PSYCHROPHILIC, EPIBIOTIC AND BIOLUMINESCENT SHEWANELLAE Very little is known about the ecophysiology of the bacteria that inhabit these niches, and virtually nothing is known about the nature of the microniches or the numbers of organisms present. Recent work by Nichols et al. (2000), and Bowman et al. (Bowman et al., 1997; Bowman et al., 2000) suggests a critical feature of the deep sea cold- and pressure-tolerant microbes is their ability to produce eicosapentaenoic acid (EPA). However the strains adapted to pressure and cold-temperature appear to be biochemically and phylogenetically related. Also, these traits appear to be associated with the ability of shewanellae to survive as epibiotic strains in the tissues of various marine animals.

Several epibiotic strains of *Shewanella* have been identified and characterized including *Shewanella marinintestina*, *S. schlegeliana* and *S. sairae* from intestines of various marine animals (Satomi et al., 2003). While *S. sairae* and *S. marinintestina* cluster closely with *S. pealeana*, *S. schlegeliana* clusters closely with *S. cowelliana*. Biochemical analysis of the epibiotic strains indicates that EPA can make up a significant portion of their unsaturated lipids (Satomi et al., 2003). Though EPA may play an important role in the

colonization of the host, there is no strong support for such a conjecture at this point. In fact there is strong evidence that the presence of EPA may be related to temperature adaptation. Recently it was demonstrated that when grown at 28°C, *Shewanella pealeana* appeared not to produce detectable levels of EPA (Leonardo et al., 1997). However, when grown at a lower temperature (20°C), the same strain was shown to produce significant levels of EPA (Satomi et al., 2003). Therefore the presence of EPA may have little direct influence on the host-epibiont relationship.

The trait of bioluminescence is found in only two species of shewanellae, *S. hanedai* and *S. woodyi*, both isolated from deep cold water, and both capable of growth at 4°C. The ability to emit visible light is consistent with location in the dark, deep sea, and given the association of *S. pealeana* with squid, a symbiotic luminous habitat for these species might be imagined. Both the mechanism of the light emission (bacterial luciferase), and wavelengths emitted are similar to that seen in the luminous vibrios and photobacteria. However, these two species were isolated as planktonic bacteria and nothing else is known of their luminous niches or ecophysiology. One item of interest is that these bacteria lack the capacity for widespread redox chemistry so characteristic of most of the other shewanellae.

Kato and Nogi (2001) have proposed that the shewanellae be divided into two groups on the basis of ability to adapt to and grow in the deep sea. This would put several closely related organisms like *S. benthica*, *S. violacea*, *S. pealeana*, *S. gelidimarina*, marine epibionts, and the luminous shewanellae into a separate subgroup, with *S. violacea* and *S. benthica* being placed in a branch with the piezophilic strains. As the authors note, this division has some difficulties, e.g., those tying the 16S rDNA sequence data to the physiological traits of the shewanellae in general. Nakasone et al. (K. Nakasone et al., personal communication) are in the process of completing the genomic sequence for one of these bacteria. As discussed later, this sequence may provide major insights into the differences among the shewanellae, as both the 16S rRNA sequence (Fig. 1) and deep-sea niche of *S. benthica* and *S. oneidensis* MR-1 are widely separated.

Isolation and Characterization of the Shewanellae

Several notable features of most shewanellae can be used for enrichment: 1) the metabolism of lactate via anaerobic respiration of several

electron acceptors including thiosulfate, nitrate and hydrous metal oxides; 2) aerobic metabolism; and 3) the production of H_2S from thiosulfate during anaerobic growth. Along with a few other groups of metal-reducing bacteria, the shewanellae can also use molecular oxygen as electron acceptors. Thus the aerobic growth cycle can be used to speed up initial enrichments, although the shewanellae are so abundant in many metal-reducing environments, and grow so well in enrichment cultures, that such procedures are not necessary. However, for teaching and demonstration purposes, enrichment cultures can be achieved with any of several general media as follows: growing organisms anaerobically using lactate (20 mM) as the carbon source, and nitrate or fumarate (5–50 mM) as electron acceptor, then transferring them first to aerobic medium with lactate as carbon source, second to anaerobic medium with thiosulfate (50 mM) as electron acceptor, and lactate as electron donor, and lastly to anaerobic medium with iron or manganese oxide (solids at approximately 100 mM) as sole electron acceptor, and lactate as electron donor. At each stage of the enrichment, the cells are plated out on metal overlay plates (see below) and the colonies are picked and checked for H_2S production. Thiosulfate-containing medium with Fe(II) is used so that any H_2S formed through thiosulfate reduction results in the formation of a black (iron sulfide) precipitate. This trait is nearly diagnostic for the shewanellae.

Precautions and Recommendations

- 1) Mn oxides are easy to reduce and may give false positives. Because Mn oxides are more quickly reduced, demonstration of Mn oxides reduction is a good teaching tool
- 2) Addition of reductants to the medium (e.g., cysteine) to lower the redox, or production of organic acids, H_2S , or Fe(II) can result in Mn(IV) reduction
- 3) Fe oxides are more stable, and difficult to reduce abiotically
- 4) Highly crystalline metal oxides (Fe or Mn) purchased from most supply houses have low surface area and low reactivity. Thus, make your own
- 5) Metal oxides (especially Mn oxides) stored in liquid suspension tend to change (coagulate and “age”) with time, leading to differences between experiments and ultimately to very unreactive metal oxides
- 6) Fe(III) can be prepared in a number of soluble forms, using chelators such as NTA (nitriloacetic acid), citric acid, ammonium citrate, or others. Such approaches reduce the

complexities seen when solid surfaces are added to experiments

Preparation of Manganese and Iron Oxides

MANGANESE OXIDES Mn oxides are in general very easy to prepare (see Kostka and Nealson, 1997). There are a number of methods, all of which produce acceptably active, amorphous or poorly crystalline MnO_2 . One method is as follows:

- 1) Dissolve 8 g of KMnO_4 in 200 ml of distilled water
- 2) Heat to 90°C while stirring continuously
- 3) Add 10 ml of 5 N NaOH
- 4) In a separate flask, dissolve 15 g of $\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$ in 75 ml of distilled water. Add this solution slowly to the basic permanganate solution. This results in a precipitate being rapidly formed
- 5) Continue heating and stirring for one hour
- 6) After cooling, the MnO_2 is washed several times by centrifugation and resuspension in distilled water
- 7) After the final resuspension, the solid is freeze dried and stored as a fine dried powder

This material is referred to as “ δMnO_2 ” or “vernadite” (Balistrieri and Murray, 1982), but unless the mineralogy is determined, it is more appropriate to refer to it as “amorphous MnO_2 ” or “manganate,” a generic term for Mn oxides of the formula MnO_2 .

If weighed subsamples are stored, they can be rehydrated to similar concentrations, and the reactivity of the manganate is reproducible. Samples can also be autoclaved before lyophilization, and stored as sterile dry subsamples for later use. A slight variation of this method is presented in Kostka and Nealson (1997).

IRON OXIDES Iron oxides range from amorphous $\text{Fe}(\text{OH})_3$ (ferrihydrite or rust), to highly crystalline forms such as goethite, and magnetite. Like the Mn oxides, the iron oxides can change with time, forming a wide range of intermediate complex forms.

A complete treatise on the preparation and properties of iron oxides is available (and recommended) if detailed knowledge of iron oxides is required (Schwertmann and Cornell, 1991). Because ferrihydrite is commonly used in enrichments, one of the many ways of preparing it (Schwertmann and Cornell, 1991) is given below.

- 1) Dissolve 40 g of $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ in 500 ml of distilled water
- 2) Add KOH (approximately 330 ml of a 1.0 M solution) to bring the pH to 7.8. As pH approaches 7.8, add last few ml dropwise with constant monitoring and stirring

- 3) Ferrihydrite suspension is centrifuged and washed six times in distilled water
- 4) Use on day of preparation, as goethite or hematite will form with age
- 5) Ferrihydrite can be lyophilized and stored dry with only minor alterations

This method gives a good general, high surface area, reactive iron oxide for enrichment cultures.

Basal Medium (M1)

M1 basal medium is used, but simply using complex medium (peptone-yeast extract media of almost any type) with lactate as the carbon source will suffice for general isolation of shewanellae. It is critical that lactate be used as the carbon source for enrichment. As far as is known, all *Shewanella* species can use lactate, which reduces competing contaminants, and also diminishes any nonspecific metal reduction due to organic acid production, etc.

M1 Medium

(NH ₄) ₂ SO ₄	1.19 g
PB	15 ml
BSS	100 ml
Distilled water	875 ml
MSS	0.1 ml
NaHCO ₃	10 ml
AA	10 ml
Carbon substrates	variable
Electron acceptors	variable

For one liter of medium, (NH₄)₂SO₄ is dissolved in a solution containing phosphate buffer (PB), basal salts solution (BSS), and distilled water in a 2-liter Erlenmeyer flask. Then, 0.1 ml of trace metals supplement (MSS) is added before adjusting to pH 7.0 with 10 N NaOH or 10 N HCl as needed. For solid media, 15 g of agar are added. After autoclaving for 20 min, some turbidity may appear, but it will clear up with cooling. The 0.2 mM NaHCO₃ solution is added after cooling and the medium stored at room temperature. Before use, amino acids (AA), carbon substrate, and electron acceptor(s) are added as desired. Ten ml of AA is usually used, while carbon sources (10–20 mM) and electron acceptors (4–100 mM) are added as needed.

To stimulate growth, the medium may be supplemented with yeast extract (0.01–0.05%), and peptone or casamino acids to similar or higher levels. The medium is normally buffered with 4-(2-hydroxyethyl)-1-piperazine-ethanesulfonic acid (HEPES) at a final concentration of 10–50 mM before adjusting the pH of the basal medium.

Phosphate Buffer

KH ₂ PO ₄	30.0 g
K ₂ HPO ₄	66.1 g
Distilled water	800 ml

Adjust to pH 7.0, and bring final volume to 1 liter. Check and adjust pH again, and store at 4°C in a plastic container (or freeze for long-term storage).

Trace Metals Supplement

CoSO ₄ · 7H ₂ O	1.41 g
Ni(NH ₄) ₂ (SO ₄) ₂ · 6H ₂ O	1.98 g
NaCl	0.58 g
Distilled water	100 ml

Autoclave for 20 min and store at 4°C.

Basic Salts Solution

Sterile MSS (see above)	10 ml
Distilled water	800 ml
MgSO ₄ · 7H ₂ O	2.0 g
CaCl ₂ · 2H ₂ O	0.57 g
Ethylene diaminetetraacetate (EDTA), disodium salt	0.20 g
FeSO ₄ · 7H ₂ O	0.012 g

Filter sterilize and store in glass bottle at 4°C.

AMINO ACID MIXTURE Add 0.2 g each of L-arginine, L-serine and L-glutamic acid to 100 ml of distilled water. Autoclave for 20 min, and store in a sterile glass bottle at 4°C.

CARBON SUBSTRATES Carbon substrates are prepared as filter-sterilized solutions of 1 M, with pH adjusted to 7.0. They are stored in glass bottles.

ELECTRON ACCEPTORS Soluble electron acceptors are prepared as stock solutions, sterilized, and stored in glass jars as sterile solutions. Insoluble electron acceptors are prepared as described above, and stored as sterile dried powders.

Applications

Bioremediation of Metal Pollutants

The shewanellae as a group have been considered excellent model systems for the study of bioremediation of toxic metals. Their ability to reduce U(VI) to insoluble U(IV), and Cr(VI) to insoluble Cr(III) have made them prime candidates for use in contaminated systems, where addition of nutrients and/or addition of microorganisms might be utilized for the *in situ* immobilization of toxic elements. Such approaches might be particularly valuable in storage tanks or other locations where high volumes of dilute waste was present. With the advent of the discovery of many other metal-reducing bacteria, it seems almost certain that this approach will be adopted for *in situ* and *ex situ* bioremediation of toxic metal contaminants. The shewanellae are well suited to some applications, being tolerant to oxygen and thus reasonably robust for intro-

duction to polluted environments of different oxygen concentrations. Some strains, but not all, have very limited versatility with regard to electron donor utilization, so success might depend on the choice of strains.

Reduction of other metals, such as the oxidized forms of selenium, arsenic, and technetium (Table 2) have also been demonstrated for some shewanellae, and may offer some yet-to-be-gained insights into the remediation of these compounds. Little has been done, other than to demonstrate these abilities. Sulfide formation has received little attention as a method for remediation of metal contamination, particularly insoluble sulfide formation as a method of removing transition and heavy metals. The shewanellae may offer some interesting variations on this theme via the production of sulfide from thiosulfate, a process that can be regulated by the addition of other electron acceptors.

Bioremediation of Organic Pollutants

With the exception of remediation of some of the methyl halides (Picardel et al., 1993; Petrovskis et al., 1994), organic pollutant remediation by the shewanellae has been little investigated. The potential of shewanellae (as a group) in the anaerobic bioremediation of organic pollutants (at the expense of iron reduction) has been largely ignored because their ability to take up and utilize complex organics is limited. Given the plethora of metal-reducing microbes (including new isolates of shewanellae) now being isolated, and their wide range of organic carbon utilization capability, it is almost certain that this process will be useful. The role(s) of the shewanellae in such processes are simply not known at this time.

Food Spoilage

The shewanellae were first isolated as food spoilage organisms, and remain important today, especially in marine systems where TMAO predominates, and where anaerobic fish spoilage is equated with TMAO reduction. The regulatory system of the shewanellae, and the controls on TMAO-dependent anaerobic respiration, are currently being investigated (Gon et al., 2002) and will have potential strong implications with regard to food spoilage.

Shewanella Strains as Expression Vectors

Ozawa and coworkers have shown that *S. oneidensis* MR-1 is an excellent vehicle for the expression of genes for heme proteins from *Desulfovibrio vulgaris* Miyazaki F (Ozawa et al., 2000), and have followed this report with more

details of the expression system (Ozawa et al., 2001). The advantage of the system shown to date is not so much that higher yields are obtained (although the yields are substantially better than in other expression systems), but that the cells can be grown rapidly to high densities under aerobic conditions, then switched to anaerobic conditions, and large amounts of protein produced. For potentially valuable cytochromes, or for proteins needed in high amounts for analysis, such a system offers obvious advantages.

Controversy and Perspectives

Piezophilic Strains

Shewanellae in the groups *S. benthica* and *S. violacea* have been isolated from a number of deep sites and been shown to be not only tolerant of high pressures and low temperatures, but in many cases, to be highly adapted to and dependent upon high pressure. The characteristics of these organisms, referred to as “piezophiles,” are reviewed in a recent paper by Kato and Nogi (2001), in which the authors propose that the shewanellae should be broken up into two subgroups, one containing the piezophilic and the other piezotolerant strains. Whether or not this suggestion stands the test of time (and more isolates with new phenotypes), the impact of these strains on our understanding of temperature and pressure as regulatory signals is unquestionable.

Requirement for Surface Attachment for Metal Reduction

One of the most interesting recent developments in understanding this system has been the realization that while the iron and manganese oxides are solids, and surface contact was necessary for reduction (according to initial reports; Myers and Nealson, 1988; Lovley et al., 1989; Caccavo et al., 1990), there are conditions under which this is clearly not the case. Lovley et al. (1996) reported a substantially increased rate of metal reduction after adding “artificial humic substances,” e.g., anthraquinone disulfonate, which acts as an electron shuttle, allowing metal reduction without bacterial/mineral contact. Newmann and Kolter (2000) followed this work with observations that shewanellae incapable of metal reduction could be crossed by wildtype cells, indicating that the shewanellae were producing reductants of their own that allowed extracellular reduction. This led to a model in which extracellular electron shuttles act as reductants (Hernandez and Newmann, 2000), and contrasts with reports indicating that specific proteins are

made by the shewanellae for attachment to metal surfaces. Given that Caccavo (1999) and Das and Caccavo (Das and Caccavo, 2000; Das and Caccavo, 2001) have shown the ability of *S. algae* to attach specifically to various surfaces, and that Lower et al. (2001) have shown physical changes upon contact with solid surfaces, it seems very likely that there will be conditions under which each approach might be favored, and studies with genomic arrays and targeted gene systems should lead to a resolution of this interesting conflict. With regard to some of the proposed applications discussed above, the use of such electron shuttles may offer particularly nice tools with which to manipulate or direct the activities of the shewanellae or other dissimilatory metal-reducing bacteria.

Distribution and Abundance of the Shewanellae

Various *Shewanella* species have been identified from a wide variety of different environments using direct isolation, enrichment cultures, and molecular identification methods. It is thus of some curiosity that a small but directed controversy appears to have arisen around the existence of this bacterial group in environments where metal reduction occurs. This issue relates to the comparative levels of members of the group called "Geobacteriaceae" (containing several genera), which are routinely found either by isolation or molecular methods in many vadose zone and ground water environments. In these environments, the shewanellae are either absent or not abundant, leading to the assertion that the shewanellae are inconsequential organisms in "areas of metal reduction" (Lovley, 2000). Surely this issue will be settled with time, but notably, the shewanellae are clearly abundant in many widespread environments where metal reduction is a major process (with metal reduction rates that may be orders of magnitude higher than those in the vadose zones). Such places include the redox interfaces of the Baltic Sea, the redox interfaces of the Black Sea, marine sediments of the Amazon, Panama and Mississippi deltas, lake sediments, and probably many others. As more is learned about these bacteria, we believe that their ecological role(s) will become clear, as will the reasons for their abundance in environments of very high metal reduction activity.

Genomics

The analysis of the MR-1 genome has already begun to have major effects on our knowledge of this organism, and with the completion of a second genome (*S. violacea* DSS12; K. Naka-

sone, personal communication), this should continue. The areas that have been impacted by the genomic information fall into two classes: first the recognition of genes and gene types within the genome that can now be specifically mutated and studied, and second the use of expression arrays to study large numbers of genes responding to changes in growth conditions. With regard to the first area, many advances can now be made that previously would have been extremely difficult and time-consuming. This will be an area of great activity, as individual systems are mutated and studied singly and in combination. As for the second area, a number of preliminary studies have already been initiated, and early results suggest that gene arrays can be routinely utilized for MR-1 (Murray et al., 2001; Beliaev et al., 2002a; Beliaev et al., 2002b; Thompson et al., 2002). The work of Murray et al. compares expression of a number of different shewanellae, using an MR-1 array. The results suggest that though some genes are highly conserved, a lot of modification has occurred, to the point that a single shewanella array for environmental work is not a feasible approach. The other reports are the beginning of a large effort to elucidate this organism's global regulation mechanisms, regarded by many individual reports as recent developments. This global approach under various physiological conditions, should lead to some resolution of how this organism interacts with its environment, including other species of bacteria.

Evolution of Metabolism

When MR-1 was isolated, and the range of electron acceptors it can utilize were recognized (Myers and Nealson, 1988), there was some excitement and anticipation that detailed study of the genes and enzymes involved in these processes might lend insights into the sequence of evolution of anaerobic respiration. As the genome of MR-1 is completed, it should be possible to recognize which genes have evolved by duplication and which acquired by horizontal transfer. The ability to extract evolutionary insights from the sequences will almost certainly be enhanced by the comparisons between the MR-1 genome and other bacteria, as well as partial or full genomes of other shewanellae (note again that the complete genome sequence of a second shewanella species, *S. violacea* strain DSS12 is nearly complete; K. Nakasone, personal communication). This deep-sea strain can grow at low and medium temperatures, and at low and high pressures. Its 16S rRNA sequence widely separates it from strain MR-1 (Fig. 1), and this strain should thus be a good candidate for comparative sequence analyses.

With regard to gene location and transfer, it was noted several years ago that a large megaplasmid (~200 kbp) is present in MR-1, and that genes involved in anaerobic respiration are present on this plasmid (Saffarini et al., 1994). These initial observations have been confirmed with the identification on the plasmid of structural and regulatory genes for respiration (Heidelberg et al., 2002). Thus, the issue of large-scale horizontal transfer of genes involved both in general anaerobic respiration and in metal reduction via such a megaplasmid must be considered. Such a possibility might account for some of the major differences seen in the different ecological groups of the shewanellae.

16S rDNA Taxonomy and Phylogeny

We would be remiss in this article not to mention the difficulties that have arisen with the genus *Shewanella* as more species have been added to the group on the basis of 16S rDNA similarities. As a result, the genus has virtually no unifying phenotypic or ecological features that can accurately define it. Classical microbial taxonomy would not have placed these organisms together, and given the differences in ecophysiology, either they will be separated into two or more genera, or other aspects of their ecophysiology will be elucidated to justify the grouping of these species into a single genus.

Acknowledgments. We would like to thank the many colleagues who responded to our request for information, in particular, Drs. Nakasone, Kato and Thamdrup, who supplied unpublished information and ideas that were of great help. Support for some of the research reported here was obtained from the National Aeronautics and Space Administration (NAI program), and the United States Department of Energy (NABIR program).

The Genus *Nevskia*

HERIBERT CYPIONKA, HANS-DIETRICH BABENZIEN, FRANK OLIVER GLÖCKNER AND
RUDOLF AMANN

Habitat

Nevskia ramosa is a conspicuous inhabitant of the air-water interface of calm freshwater bodies. Its typical habitat forms by virtue of the dipole character of water molecules and their anisotropic positioning at the surface. The water surface has a high surface tension. Therefore, hydrophobic microlayers develop which accumulate organic molecules. The interface harbors a microbial community referred to as “the neuston” (Naumann, 1915). Members of the neuston community can be subdivided into those living underneath the interface, called “hyponeuston,” and those residing on the surface, the so-called “epineuston.” *Nevskia ramosa* is a member of the epineuston. It forms opaque pellicles on the water surface. These are so hydrophobic that little water droplets sprayed on them (as on paraffin) keep their spherical shape (Pladdies et al., 2004). Since the air-water interface is exposed to sun radiation, an essential adaptation to life in the neuston layer is ultraviolet (UV) tolerance.

Nevskia ramosa has been discovered in the surface pellicle of aquarium water (Famintzin, 1892). Later on it was detected in various natural environments including swamps, soil, ponds, ditches, lakes and several artificial habitats (Henrici and Johnson, 1935; Babenzien, 1965; Babenzien and Schwartz, 1970; Hirsch, 1999; Babenzien and Cypionka, 2004; Pladdies et al., 2004). There are no reports on the occurrence of *Nevskia ramosa* in seawater with the exception of one observation in brackish water of the Bight of Kiel (Baltic Sea; Zimmermann, 1975).

Nevskia develops to high population densities during calm weather periods. More than 20,000 cells per cm² were detected on a lake after three weeks of calm summer weather. After a rainy period and deeper in the water column, the cell numbers of *Nevskia* were much lower (Pladdies et al., 2004).

Morphology

Single cells of *Nevskia ramosa* are rod-shaped, often slightly bent and stain Gram-negative. In

the older literature, there are differing values for the cell size. Cells studied after phylogenetic identification (see below) in recent reports were 0.7–1.1 × 1.5–2.3 μm (Stürmeyer et al., 1998; Glöckner et al., 1998; Pladdies et al., 2004). Often the cells contain refractive globules, probably polyhydroxyalkanoates (Babenzien and Hirsch, 1974).

The most conspicuous feature of the cells is the laterally excreted slime stalk formed when the cells spread out on the water surface (Fig. 1A and B). The stalks show annual ring-like patterns that indicate growth in intervals. The exopolysaccharide of the stalks consists mainly of rhamnose and small amounts of glucose and mannose (Stürmeyer et al., 1998). It is unknown how their hydrophobicity is brought about. The characteristic stalks are, however, not always present. The cells can run through a lifecycle as described by Babenzien (1967): Young cells are motile by a polar flagellum and develop submersed, then adsorb to the water surface, lose their flagellum, and form hyaline slime stalks at the concave side of the cell. The stalks stay connected but branch when the cells multiply by binary fission. Thereby flat rosettes form that can reach a size of 80 μm in diameter (Babenzien and Cypionka, 2004). A typical rosette with 16 cells may cover an area of about 700 μm² (Pladdies et al., 2004). On agar plates, geometrical patterns of slime-coated cells were observed instead of the typical flat rosettes.

The development of surface pellicles depends on the availability of combined nitrogen. If ammonia, nitrate or amino acids are supplied, the cultures grow submersed (see below).

Growth Medium

Nevskia ramosa can be cultivated as surface film in a simple synthetic medium of the following composition (values in mM; Stürmeyer et al., 1998): sodium lactate, 5; MgSO₄ · 7H₂O, 0.2; CaCl₂ · 2H₂O, 0.1; KH₂PO₄, 25; trace element solution SL 9 (Tschech et al., 1984), 0.5 ml · liter⁻¹; vitamin solution (Pfennig, 1978), 0.5 ml · liter⁻¹; and pH adjusted to 7.0. Cultures are incubated at

Fig. 1. *Nevskia ramosa* microcolonies stained with safranin (A), toluidine blue (B), and cells identified by means of the species-specific rRNA probe NEV656 (C). Bar, 25 μ m.

room temperature (20–25°C) without shaking. The special feature of this medium, which induces growth in the surface film, is the lack of nitrogen compounds. If submersed growth of a culture is desired, the medium is supplemented with 5 mM NH_4Cl .

Identification

Different from most other bacteria, *Nevskia* can be identified microscopically because of its typical habitat and microcolony form. If a pellicle from a freshwater aquatic environment contains the typical flat, dichotomously branched and hydrophobic microcolonies with single cells in the tips, one can be quite sure to have *Nevskia ramosa*. However, in the neuston layer there might be other types of stalk-forming bacteria with three-dimensional microcolonies. These belong to the hyponeuston and are not *Nevskia ramosa* (Pladdies et al., 2004).

The polysaccharides of the stalks can be stained with toluidine blue (0.1% in distilled water) or safranin (0.1–0.5% in distilled water). Staining is performed on slides covered with gelatin (0.1%) and CrKSO_4 (0.01%). After spreading of the biofilm, the slide is dried under air, then stained for 30 min, and washed with distilled water (Stürmeyer et al., 1998).

A reliable identification is possible by fluorescence *in situ* hybridization (Fig. 1C). Glöckner et al. (1998) have designed and evaluated two probes, NEV656 (CGCCTCCCTCTACCGTTT, binding to the positions 656–674 of the small subunit [SSU] ribosomal RNA) and NEV177 (GCTCTTGCGAGATCATGC, binding to the positions 177–195 of the SSU ribosomal RNA), which turned out to be specific for *Nevskia ramosa*.

Ecophysiology

Nevskia ramosa has a strictly aerobic metabolism and grows with broad range of organic compounds including monomeric sugars, sucrose, starch, cellulose, organic acids, ethanol, amino acids, benzoate and Tween 20 or Tween 80 (Stürmeyer et al., 1998). It shows weak catalase, but no cytochrome oxidase activity. Cytochromes of the *b*- and *c*-type are present. Nitrogenase activity was not detected.

As mentioned above, rosette formation depends on the availability of nitrogen compounds. The cells do not form rosettes during growth with amino acids, or when ammonia is added to the growth medium. It is well known that under nitrogen limitation and carbon surplus, bacteria form reserve material like polyhydroxyalkanoate globules and extracellular polysaccharide slime. Once spread over the surface in the biofilm, *Nevskia* cells have a good chance to trap ammonia from the air. Thus, rosette formation appears to be caused by nitrogen deficiency, but at the same time represents a mechanism to overcome it.

Growth in hydrophobic films stabilizes the positioning of the rosettes. Furthermore, the bacteria might be protected against grazers that cannot permeate the interface and are unable to take up cells by phagocytosis.

The open exposure to sunlight might cause DNA damage. However, *Nevskia ramosa* was found to have a very effective photorepair mechanism. The number of cells surviving UV radiation of 254 nm increased by seven orders of magnitude if the cells were exposed to light of 350 nm after the UV treatment (Stürmeyer et al., 1998). Since under natural conditions UV radiation is always combined with white light, *Nevskia* appears to be well prepared to survive sun radi-

ation. However, no positive enrichments were obtained from the site with the highest UV exposure (i.e., an alpine lake located at 2413 m above sea level; Pladdies et al., 2004).

Enrichment and Isolation of Pure Cultures

Nevskia can easily be enriched from freshwater surface pellicles on the medium described above or most simply on sterilized water from the habitat supplied with 5 mM lactate. Samples for inoculation are collected on sterile glass slides or loops. The cells have doubling times of 2–4 days and require 2–4 weeks for development of the typical rosettes of dichotomously branched slime stalks with single cells in the tip. Growth can also be monitored in a hanging drop (Stürmeyer et al., 1998).

Pure cultures can be obtained by repeated streaking on plates with the same medium and agar (1%, w/v). On agar, *Nevskia* does not develop the characteristic rosettes. Instead, geometrical patterns of slime-coated cells are typical (Stürmeyer et al., 1998). However, pure cultures

form the characteristic microcolonies if brought back to ammonia-free liquid medium.

Phylogeny

The DNA base composition of the DNA was 67.8 ± 0.1 mol% G+C for *Nevskia ramosa* strain Soe1 and 69.0 ± 0.2 mol% G+C for strain OL1 (Stürmeyer et al., 1998).

The phylogenetic analysis of the 16S rRNA indicates that *Nevskia ramosa* has no near relatives known so far. Currently, this species is the sole representative of a deep branch of the Gammaproteobacteria (Fig. 2). It is not closely related to other stalk-forming bacteria like the Alphaproteobacterium *Caulobacter crescentus* (83% similarity) or the Betaproteobacterium *Gallionella ferruginea* (85% similarity).

So far the genus has only one species, *Nevskia ramosa*. Two strains, *N. ramosa* Soe1 (DSM 11499^T) and strain OL1 (DSM 11500) were deposited at the Deutsche Sammlung von Mikroorganismen und Zellkulturen, Braunschweig, Germany. Different isolates (Stürmeyer et al., 1998; Pladdies et al., 2004) and clones with the

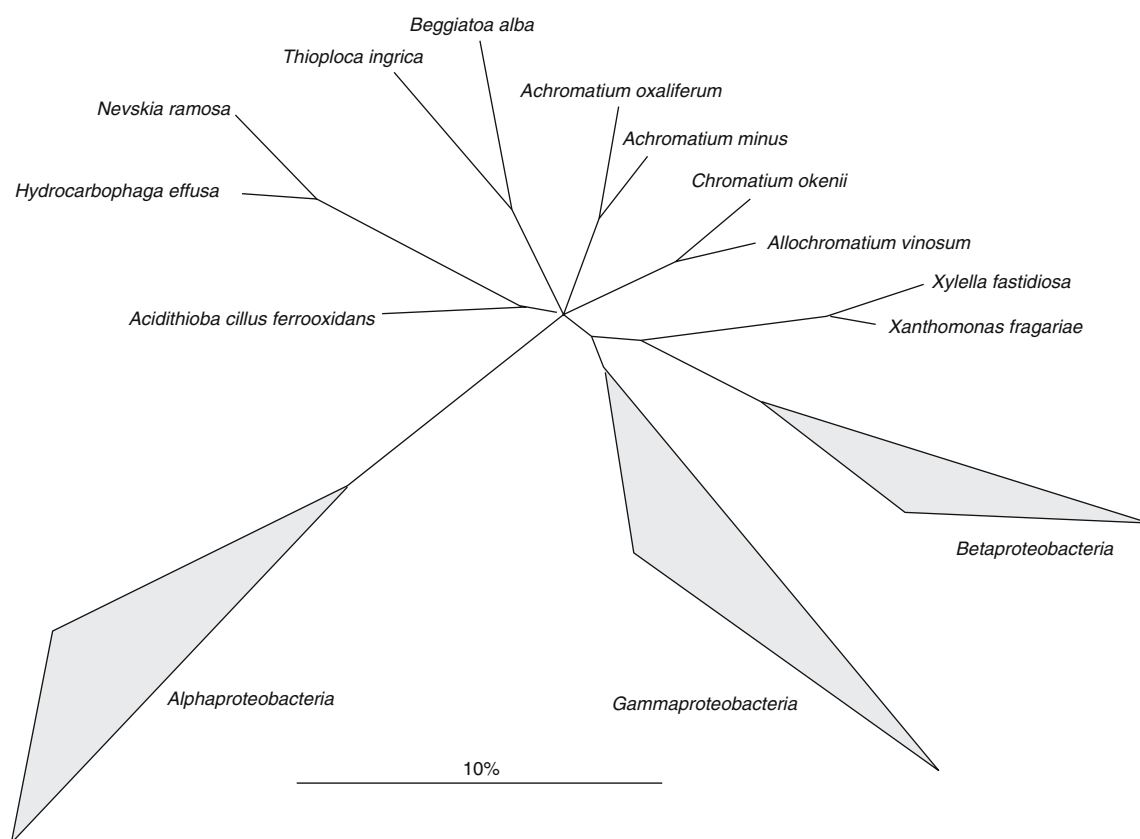

Fig. 2. Phylogenetic tree based on 16S rRNA gene sequences showing *Nevskia ramosa* branching deeply at the gamma-subclass of the Proteobacteria.

16S rRNA gene (Glöckner et al., 1998) of *Nevskia ramosa* showed very similar sequences (at least 98% similarity). However, genomic fingerprints generated by enterobacterial repetitive intergenic consensus sequence–polymerase chain reaction (ERIC PCR) showed different banding patterns with all isolates, thus indicating some genetic diversity within the species.

The Genus *Thiomargarita*

HEIDE N. SCHULZ

Introduction

Thiomargarita namibiensis is by far the largest member in the group of “morphologically conspicuous sulfur bacteria” (La Riviere and Schmidt, 1992). This group harbors sulfur storing, colorless bacteria, which gain energy by the oxidation of sulfide and can be readily recognized by their very particular morphology. The spherical cells of *Thiomargarita* are typically 100–300 μm wide, but with some regularity, very large cells with diameters of up to 750 μm occur (Schulz et al., 1999). Therefore, *Thiomargarita namibiensis* is, at least in terms of volume, the largest bacterium known so far. Nevertheless, it was one of the last sulfur bacteria to be discovered (Schulz et al., 1999). This may be because this organism seems to occur only in shelf sediments off the coast of Namibia, where it inhabits a sulfidic loose sediment composed of mainly dead diatoms, which is regularly suspended (Weeks et al., 2004) by methane eruptions (Emeis et al., 2004). In contrast to their close relatives *Beggiatoa* and *Thioploca* (The Genera *Beggiatoa* and *Thioploca* in this Volume), *Thiomargarita* cells do not form filaments, but the single cells are held together in a string by a mucous sheath (Fig. 1). This appearance inspired the name “sulfur pearl of Namibia.”

In spite of their large size *Thiomargarita* cells are less conspicuous to the naked eye than their smaller relatives *Thioploca* and *Beggiatoa* because the individual chains do not cling together in bundles or mats but rather appear as short white lint, scattered throughout the upper centimeters of the sediment (Fig. 2). Nevertheless, they can build up very dense populations of up to 200 g m⁻² sediment (Brüchert et al., 2003), which are comparable in biomass to the dense mats of *Thioploca* spp. off the South American west coast. In both cases the high abundance of sulfur bacteria is due to a special oceanographic situation, called “upwelling,” which leads to active primary production in the water column and large amounts of organic material being deposited on the sea floor.

The elevated availability of organic carbon in sediments of upwelling areas is the cause for exceptionally high rates of sulfate reduction, leading to an accumulation of sulfide, which supports the populations of sulfur bacteria. Under these highly reducing conditions oxygen is hardly ever available and cannot be used as electron acceptor for the oxidation of sulfide. Instead *Thiomargarita* and the larger species of *Thioploca* and *Beggiatoa* use nitrate as electron acceptor, which they can take up at the sediment surface and concentrate in a vacuole. With this stock of nitrate they can oxidize sulfide in the sediment. *Thiomargarita* is not motile but relies on a resuspension of the sediment into the nitrate-containing bottom water. This passive life mode is the reason for the large size of these bacteria. Most of their volume is taken up by the vacuole, which enables them to survive long intervals in sulfidic sediments.

Identification and Taxonomy

Thiomargarita namibiensis is characterized by very large cells (100–300 μm in diameter), which contain numerous sulfur inclusions. The mostly spherical (Fig. 3A), sometimes barrel-shaped (Fig. 3B) cells are held together in a string by a common mucus sheath, but individual cells are not connected to form a true filament, as in the filamentous relatives *Beggiatoa* and *Thioploca* (The Genera *Beggiatoa* and *Thioploca* in this Volume). The diameter of cells within a string is mostly similar. The individual strings may coil up to form a ball and occasionally show branches. The cells appear hollow inside owing to a central vacuole that takes up most of the volume. Motility has not been observed.

The great majority of cells seem to divide in one plane (Fig. 4A). Frequently, all the cells within a string seem to be in the same state of division (e.g., Fig. 4B), suggesting a possible synchronization between neighboring cells. In Namibia large cells dividing in two planes have been observed very seldom, (Fig. 4C), whereas

Fig. 1. A string of *Thiomargarita namibiensis* cells as seen in the stereomicroscope. The single cells are about 150 μm in diameter. The many light scattering sulfur inclusions are responsible for the white color of the cells.

Fig. 2. A Petri dish of 8.6 cm diameter containing surface sediment from the Namibian shelf. Strings of *Thiomargarita* cells are visible as white lint (arrows).

Thiomargarita cells from the Gulf of Mexico regularly divided in more than one plane (Kalanetra et al., in press). The mucus between newly divided cells is very thin (Fig. 4B) but keeps accumulating over time, leading to a breakage of longer chains. Spherical cells tend to form shorter chains of typically, 4–20 cells, while barrel-shaped cells may form very long chains of 50 cells or more. Occasionally, cells with an aberrant shape can be observed. These cells are either abnormally large (up to 750 μm) or show many irregular bulges.

Fig. 3. Cell shape: A) Spherical cells. B) Barrel-shaped cells.

Within very dense population of *Thiomargarita namibiensis*, big white clusters of numerous small white cells occur regularly. These clumps of cells, which were first noticed by Michelle Graco, resemble cauliflower (Fig. 5A). Viewed under the light microscope, the small cells are shaped like *Thiomargarita* cells and also contain sulfur inclusions but are much smaller and less transparent (Fig. 5B), possibly because of a thicker cell wall. These small cells could be survival stages of *Thiomargarita namibiensis* or a different, so far undescribed species.

Cell Structure

Under the light microscope, *Thiomargarita* cells appear hollow and contain large sulfur globules as well as numerous smaller inclusions (Fig. 6). Examination with X-ray absorption spectroscopy (Prange et al., 2002) revealed that the sulfur in the globules is mainly cyclooctasulfur. The same crystalline structure of sulfur has also been found in vacuolated *Beggiatoa* and *Thioploca* filaments (Pasteris et al., 2001).

Transmission electron micrographs reveal that the actual cytoplasm of the cells is restricted to a very thin layer (0.5–2 μm just inside the cell wall; Fig. 7). Most of the cell volume (98% on average) is taken up by a liquid vacuole. The cytoplasm is not a homogenous thin layer but shows a loose, spongy structure with many round voids that are probably the remains of the large sulfur inclusions that dissolve during the preparation of samples for electron microscopy (Fig. 7B and C). Apart from the sulfur globules, numerous smaller electron dense inclusions are visible (Fig. 7B–D) that resemble polyphosphate.

Fig. 4. *Thiomargarita* cells in division: A) A cell dividing in one plane. B) Synchronized division within a string leading to pairs of cells. C) A cell dividing in two planes.

Fig. 5. White clumps made up by numerous smaller cells. A) A cluster of cells as seen in the stereomicroscope (white arrow). For comparison two regular cells of *Thiomargarita* are visible in the lower left side. B) Small cells of a cluster as seen in the light microscope. The cells appear darker than regular cells of *Thiomargarita*.

Fig. 6. A single cell of *Thiomargarita namibiensis* in the light microscope: Apart from the large sulfur globules numerous smaller inclusions are visible. The cell appears hollow.

Specific staining of the cells indicated both polyphosphate and glycogen inclusions (Schulz and Schulz, 2005).

The ultrastructure of these giant cells is not only complex with respect to the distribution of cytoplasm but also in terms of nucleic acid. When cells are stained with DAPI (4'-6 diamino-2 phenylindole) and viewed with high resolution in the confocal laser scanning microscope, the DNA is not equally distributed over the whole cytoplasm but occurs in small clumps (Fig. 8). A similar phenomenon has also been observed in another giant bacterium called "*Epulopiscium*," a gut symbiont of surgeonfish (Robinow and Angert, 1998). Possibly, the formation of nucleoids is necessary to regulate very large bacterial cells.

Phylogeny

A phylogenetic characterization of *Thiomargarita namibiensis* was difficult to achieve. Direct sequencing of the 16S rRNA gene resulted in

Fig. 7. Transmission electron micrographs showing the ultrastructure of *Thiomargarita namibiensis*: A) The cytoplasm has a spongy structure covering the outer 0.5–2 μm of the cell. B) and C) The larger voids are probably remains of sulfur globules. D) The small electron dense inclusions resemble polyphosphate inclusions. Courtesy of Mariona Hernández Maríné.

Fig. 8. Confocal laser scanning micrograph of a *Thiomargarita* cell stained for nucleic acid with 4,6-diamidino-2-phenylindole (DAPI). The DNA is not distributed equally over the entire cytoplasm but concentrated in small clumps (arrows). S = sheath.

mixed sequences because of the many different bacteria that inhabit the mucus sheath of these cells. In situ hybridization revealed that *Thiomargarita* belongs to the Gammaproteobacteria

and a specific probe designed for marine *Thioploca* species (probe 829; Teske et al., 1995) gave a positive hybridization signal, indicating a close phylogenetic relation between *Thiomargarita* and vacuolated *Thioploca*. This probe was used as a specific primer to sequence at least a part of the 16S rDNA (positions 24–828). A phylogenetic tree based on this partial sequence confirmed that *Thiomargarita* is the closest relative to the large vacuolated species of *Beggiatoa* and *Thioploca* (Fig. 9). Thus, the vacuolated, nitrate-storing sulfur bacteria appear to form one evolutionary branch within the Gammaproteobacteria (for more details, see The Genera *Beggiatoa* and *Thioploca* in this Volume). Nevertheless, complete sequences of several vacuolated sulfur bacteria from different habitats will be needed to confirm this preliminary result.

Enrichment

Until now all attempts to cultivate *Thiomargarita namibiensis* or any of the larger vacuolated species of *Thioploca* and *Beggiatoa* in pure culture have failed. This may in part be due to the relatively slow growth rates of these large cells but also may reflect ignorance of the exact optimum growth conditions.

Nevertheless, enrichment and maintenance of *Thiomargarita namibiensis* is relatively simple.

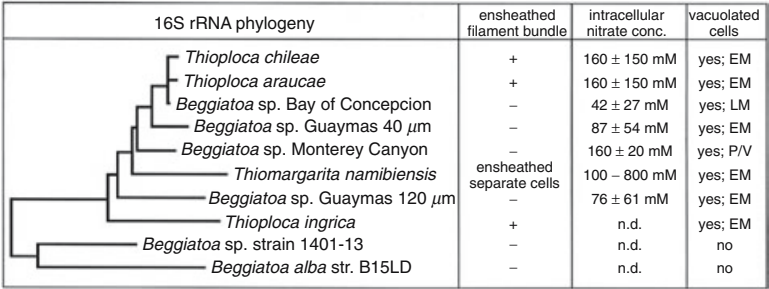

Fig. 9. Distance tree of *Thiomargarita namibiensis* and related sulfur-oxidizing bacteria of the Gammaproteobacteria. The distance tree is based on 16S rRNA position 28–828. EM = electron microscopy, LM = Light microscopy, and P/V = ratio of protein to volume. Courtesy of Andreas Teske.

Thiomargarita cells can survive in their original sediment for years as long as the activity of sulfate reducing bacteria remains moderate and sulfide concentrations in the sediment do not become toxically high. The longest maintenance of *Thiomargarita* has been achieved by pouring out only the loose top part of the sediment into a plastic bottle. The total height of the sediment in the bottle should be 1–3 cm, covered by a thin layer of seawater (<1 cm). The bottles should be kept at 4–10°C. Occasional suspension and contact with atmospheric oxygen concentrations clearly stimulates growth. To induce new growth in sediments where most of the *Thiomargarita* cells have died, resuspend the sediment several times in fresh seawater and remove the overlying water after the sediment has settled. Additionally, nitrate can be added in low concentrations (<1 mM). After longer storage times (>1 year), the activity of sulfate reducing bacteria in the sediment may decline to a point where growth of *Thiomargarita* is limited. In this case, the sediment may be transferred into a plastic bottle with a 1 cm layer of agar containing sulfide (≤0.5 mM). This procedure may result in newly developing dense populations of *Thiomargarita* but bears a high risk of losing the enrichment, owing to the build up of toxically high sulfide concentrations. The addition of acetate or cellulose to stimulate sulfate reduction cannot be recommended.

Habitats

Currently, the name *Thiomargarita namibiensis* seems to be well chosen because very dense and continuous mats of this bacterium have only been found in the Namibian shelf region (Schulz et al., 1999; Brüchert et al., 2003), but recently more locally restricted populations of another *Thiomargarita* species have been reported from hydrocarbon seeps in the Gulf of Mexico (Kalanetra et al., 2005). Even off Namibia, *Thiomargarita* is not found everywhere on the shelf but is restricted to a special sediment type, covering an area of ca 18,000 km² (Emeis et al., 2004), that

Fig. 10. A Namibian stamp from February 2003 celebrating recent biological discoveries in Namibia.

is formed almost entirely of dead diatoms. This diatomaceous ooze, which develops because of the extraordinary high primary production off Namibia, is almost completely fluid and rich in organic material. Consequently, sulfate reduction rates in these sediments can be extremely high (Brüchert et al., 2003). In one case, rates of 62 mmol m⁻² day⁻¹ (integrated over the upper 16 cm) have been reported, leading to a depletion of sulfate in sediment depths below 6 cm and sulfide concentrations of 22 mM (Brüchert et al., 2003). In about 8% of the area covered with diatomaceous mud, there is free gas (presumably

methane) accumulated underneath the sediment in shallow depths of several tenths to a few meters (Emeis et al., 2004). At least monthly, the gas erupts from these sediments (Weeks et al., 2004), carrying large amounts of sulfide into the water column and stripping the water of oxygen (Weeks, 2002). Exceptionally high biomasses of *Thiomargarita* often occurred within or in the vicinity of areas where a larger part of the sediment contained free gases underneath the surface (Vogt, 2002). This seems to suggest that the *Thiomargarita* populations might profit from regular sediment suspension triggered by gas eruptions.

Physiology

In general, *Thiomargarita* seems to share a common physiology with their closest phylogenetic relatives, the large, vacuolated *Beggiatoa* and *Thioploca*, as all of these three genera accumulate sulfur and nitrate internally. In the absence of pure cultures, this observation remains the main argument for the concept that these bacteria are gaining energy through the oxidation of sulfide with nitrate. Nevertheless, there are two notable differences between *Thiomargarita* and the vacuolated species of *Beggiatoa* and *Thioploca*: a lack of motility and tolerance for oxygen. *Thiomargarita* cells endure exposure to full atmospheric oxygen concentrations, whereas *Thioploca* populations decline when oxygen concentrations are above 3 μM (Schulz et al., 2000), and *Beggiatoa* mats thrive under local oxygen concentrations of 1–2.5 μM (see The Genera *Beggiatoa* and *Thioploca* in this Volume). Apart from tolerating oxygen, experiments measuring microgradients around single cells have shown that *Thiomargarita* can also use oxygen as elec-

tron acceptor for the oxidation of sulfide (Schulz and de Beer, 2002).

Unlike their filamentous relatives, *Thiomargarita* is not motile. Therefore, they cannot actively move to the sediment surface to take up nitrate from the overlying water, as is the case for *Beggiatoa* and *Thioploca* (The Genera *Beggiatoa* and *Thioploca* in this Volume). Nevertheless, *Thiomargarita* cells contain nitrate in up to 0.5 M concentrations. As nitrate is absent in the sediment, the cells must have access to the overlying water in regular intervals, to accumulate nitrate internally. The means of this passive access to the water column are not yet clear. Possibly, *Thiomargarita* gets regularly suspended through methane eruptions (Emeis et al., 2004; see the previous section Habitat in this Chapter). During suspension within the water column, the cells may come into full contact with atmospheric oxygen concentrations, which explains why, unlike *Beggiatoa* or *Thioploca*, *Thiomargarita* has to be oxygen tolerant.

Until now no one has conclusively shown whether *Thiomargarita* reduces nitrate dissimilatory to ammonia or to nitrogen gas. This question is difficult to address because *Thiomargarita* has not yet been isolated in pure culture. Experiments with *Thiomargarita* cells in their natural sediments under in situ conditions showed a release of ammonia over time (M. Graco and H. N. Schulz, unpublished data), but ammonia may also be released when organic material is degraded in the sediment. On the other hand, *Thiomargarita* cells that were removed from the sediment and pre-incubated with ^{15}N -labeled nitrate showed a build up of ^{15}N -labeled nitrogen within hours (S. B. Joye and H. N. Schulz, unpublished data). But it cannot be ruled out that this build up was due to the activity of denitrifying bacteria on the sheaths. In general,

Fig. 11. Physiology of *Thiomargarita*: During most times the immobile cells are within the highly sulfidic sediment without access to nitrate in the overlying water. Only when the sediment is suspended can *Thiomargarita* gain access to nitrate in the bottom water, but this access may also expose cells to higher oxygen concentration.

experiments on *Thiomargarita* cells removed from the sediment, washed, and incubated in artificial media, can easily lead to misleading data because judging whether the cells are still physiologically active is difficult, as they lack motility and may survive unsuitable conditions for long intervals. This problem was partly overcome by measuring gradients around single *Thiomargarita* cells with oxygen and sulfide microelectrodes (Schulz and de Beer, 2004). In these experiments the build up of a steep gradient around the cells revealed instantly when the cells were metabolically active. Both stable oxygen and sulfide gradients, indicating an active uptake, persisted for several hours, if acetate was added in low concentrations (10 μM) to the medium. This indicates that at least under these experimental conditions *Thiomargarita* cells were not able to fix CO_2 .

In addition to the oxidation of sulfide with nitrate or oxygen *Thiomargarita* cells may also gain energy by the brake down of internally stored polyphosphate (Schulz and Schulz, 2005). Phosphate release could be induced experimentally under anoxic conditions by adding acetate to the medium, indicating that the energy stored in the polyphosphate was used to take up and store acetate, e. g. in the form of glycogen.

Ecology

The special ecological niche occupied by *Thiomargarita* seems to be defined by their immense capacity for storing electron acceptor and donor, as well as their ability to survive long intervals under redox conditions that range from fully oxic to anoxic with sulfide concentrations of 20 mM (Brüchert et al., 2003). In contrast to their very mobile relatives, *Beggiatoa* and *Thioploca*, which constantly glide back and forth between sediment and water column (The Genera *Beggiatoa* and *Thioploca* in this Volume), *Thiomargarita* cells can only survive in an environment that oscillates between oxidizing and reducing conditions.

As these sulfide-oxidizing bacteria are present in such high biomasses, *Thiomargarita* should affect the flux of sulfide from the sediment into the open water. Astonishingly, a pronounced decline of sulfide concentrations within sediments densely populated by *Thiomargarita* has not been observed (Brüchert et al., 2003). In contrast to this, sediments populated by *Thioploca* contain almost no sulfide (Fossing et al., 1995), and *Beggiatoa* mats reduce sulfide fluxes out of the sediment significantly (see The Genera *Beggiatoa* and *Thioploca* in this Volume). Experiments on single *Thiomargarita* cells showed greatly enhanced uptake rates of sulfide when

oxygen was present in the medium (Schulz and de Beer, 2002). These observations raise the question of whether *Thiomargarita* cells might be metabolically most active during exposure to oxygenated seawater and, to survive, least active when they are buried in sulfidic sediments. Apart from the more obvious ecological importance of *Thiomargarita* for the sulfur and nitrogen cycles, it also plays an important role in the phosphorus cycle of the sediment. *Thiomargarita* has been found to release phosphate in anoxic sediments with very high rates leading to the spontaneous precipitation of phosphorus-containing minerals (Schulz and Schulz, 2005). As Namibia is one of the major areas where modern phosphorite is formed, these bacteria may play an important role in the long-term removal of phosphorus from the biosphere.

Although *Thiomargarita* strongly dominates the diatomaceous sediments on the Namibian shelf, they share this environment with other sulfur bacteria. Towards the sides of the fluid diatomaceous mud, thick mats of vacuolated *Beggiatoa* cover the sediment, whenever there is oxygen in the bottom water. Occasionally, sparse populations of *Thioploca* can be observed (Gallardo et al., 1998). Sometimes all three genera of vacuolated sulfur bacteria can be found in the same sediment, with the *Beggiatoa* forming a mat directly at the surface, the *Thiomargarita* being scattered throughout the fluid mud underneath, and the *Thioploca* penetrating the more solid sediments below the mud. Additionally, thin *Thiothrix* filaments are sometimes attached to the sheaths of *Thiomargarita* cells.

Fig. 12. A *Thiomargarita* cell covered with filamentous bacteria growing on the sheath.

In general the mucus sheaths of *Thiomargarita* cells are inhabited by an abundance of different bacteria (Fig. 8). The most conspicuous of these epiphytes are long filaments, which cover the majority of *Thiomargarita* cells (Fig. 12). Morphologically these filaments strongly resemble *Desulfonema* spp., a sulfate reducing bacterium, which frequently covers the mucus sheaths of *Thioploca* filaments (Fukui et al., 1999).

Aeromonas, 500, 510
Agarobacterium, 503
Alginobacter, 503
Alginomonas, 503
Alginovibrio, 503
Allomonas, 500
Beneckea, 500–501
characteristics of, 497
Enhydrobacter, 501
Enterobacteriaceae and, 495
evolutionary pathway of, 498
habitats of, 503
Halomonas, 501–2

- history, nomenclature, and classification of, 495–99
- identification of, 504–5
- isolation of, 503–4
- Listonella*, 502
- Lucibacterium*, 502
- nucleic acid and protein based classification, 497–99
- Oceanomonas*, 502
- Photobacterium*, 500, 510
- Plesiomonas*, 500, 510, 580
- Shewanella*, 502, 1133
- Vibrio*, 500, 510
- Virulence factors
 - Aeromonas*, 567
 - Francisella*, 1123–24
 - Klebsiella*, 168–73
 - Legionella*, 1007–11
 - Moraxella catarrhalis*, 972–74
 - Morganella*, 258
 - Pasteurella*, 1075–78
 - Plesiomonas*, 582
 - Proteus*, 253–57
 - Providencia*, 261
 - Pseudomonas*, 672–73
 - Pseudomonas aeruginosa*, 705–9
 - Salmonella*, 125
 - Xenorhabdus*, 486–87
 - Yersinia*, 346–51
 - Yersinia enterocolitica*, 280–82
 - Yersinia pestis*, 400, 414, 418, 423, 430–32
- Virulence plasmid, *Salmonella*, 134, 136, 143
- Volcaniella*, 811
- Volcaniella eurihalina*, 812, 815

W

- Wastewater environment
 - Acinetobacter*, 748, 755
 - Chromatiaceae, 854, 867
 - Klebsiella*, 165–66
 - Lysobacter*, 950
 - Psychrobacter*, 921
- Water environment
 - Acinetobacter*, 748, 754
 - Azomonas*, 759, 769
 - Azotobacter*, 759, 762–63, 767
 - Azotobacteraceae, 759
 - Francisella*, 1122
 - Pseudomonas*, 646, 652
 - Pseudomonas aeruginosa*, 705
- Wigglesworthia*, 32
- Wigglesworthia glossinidia*, 32
- Wobachia*, 1119
- Wobachia persica*, 1119
- Wolinella*, 510
- Wood habitat
 - Enterobacter*, 202
 - Klebsiella*, 165–66
- Wound infections
 - Acinetobacter*, 754
 - Citrobacter*, 93
 - Edwardsiella*, 81–84
 - Hafnia*, 215
 - Halomonas*, 829
 - Klebsiella*, 168

- Vibrio*, 514
- Vibrio metschnikovii*, 548
- Vibrio vulnificus*, 546–47

X

- Xanthomonas*, 649, 887
- Xanthomonas campestris*, 721
- Xanthomonas maltophilia*, 844
- Xanthomonas oryzae*, 202
- Xanthomonas translucens*, 725
- Xenorhabdus*, 5, 25–26, 32–34, 54, 451–56, 470, 473–88
 - applications of, 456, 488
 - characteristics of, 454, 474–76
 - cultivation of, 479–80
 - disease from, 488
 - ecology of, 487
 - genetics of, 485–87
 - genes and proteins, 485–86
 - regulation of phase variation and virulence factors, 486–87
 - habitats of, 452–53, 477–78
 - identification of, 479
 - isolation of, 478–79
 - morphology of, 476, 479–81
 - phylogenetic tree of, 452, 473
 - phylogeny of, 473
 - physiology of, 453–56, 480–85
 - convergence, 456
 - lysogeny and bacteriocinogeny, 482–85
 - phase variation, 453–56, 480–81
 - secondary metabolite production, 481–83
 - swarmer cells, 481
 - preservation of, 480
 - species of, 34, 476, 478
 - taxonomy of, 451–52, 473–76
 - genus and species delineation, 473–74
 - genus characteristics, 474–76
 - nomenclature, 473
- Xenorhabdus beddingii*, 474, 476, 480, 482, 485
- Xenorhabdus bovienii*, 452, 454, 474, 476–77, 482, 485, 488
- Xenorhabdus japonica*, 452, 474, 476
- Xenorhabdus japonicus*, 33
- Xenorhabdus luminescens*, 25, 32, 451, 456–57, 473
- Xenorhabdus nematophila*, 452–54, 474, 476, 480–82, 484–86, 488
- Xenorhabdus nematophilus*, 6, 25, 32–33, 471
- Xenorhabdus nematophilus* subsp. *beddingii*, 32–33, 476
- Xenorhabdus nematophilus* subsp. *bovienii*, 32–33, 476
- Xenorhabdus nematophilus* subsp. *nematophilus*, 32–33
- Xenorhabdus nematophilus* subsp. *poinarii*, 32–33, 476
- Xenorhabdus poinarii*, 33, 452, 474, 476, 480, 485
- Xylella fastidiosa*, 672, 674
- Xylophilus*, 741–44

- cultivation of, 742–43
- epidemiology of, 743–44
- habitats of, 741
- identification of, 742
- isolation of, 741–42
- pathogenicity of, 744
- phylogenetic tree of, 742
- phylogeny of, 741
- physiology of, 743
- preservation of, 743
- taxonomy of, 741
- Xylophilus ampelinus*, 741–44

Y

- Yersinia*, 54, 270–368, 451, 673
 - characteristics of, 281
 - effector proteins and host responses, 322–24
 - cytoskeleton as target, 322
 - inflammatory response down regulation, 322–23
 - virulon gene transcription regulation, 323–24
 - YopM, 323
- high-pathogenicity island, 327–31
 - characteristics of, 327
 - genetic organization of, 327–29, 418
 - mobility of, 329–30
 - presence in Enterobacteria species, 330–31
 - role of, 329
- history of, 270–71
- immunology of, 351–58
 - acquired immunity, 354–56
 - host defense against pathogens, 351–52
 - host defense at mucosal sites, 352–54
 - reactive arthritis, 356–58
- lipopolysaccharide, 333–44
 - biosynthesis of, 334, 363–68
 - chemical structures of, 334, 336–40
- enterobacterial common antigen, 334–35
 - genetics of, 335, 341–42
 - regulation of, 342–43
 - role in virulence, 344
- pathogenesis of, 317–51
 - high-pathogenicity island, 327–31
 - invasin, 331–32
 - lipopolysaccharide, 333–43
 - pYV virulence plasmid, 318–26, 358, 360
 - superantigens, 343–46
 - urease, 332–33
 - virulence factors, 346–51
- physiopathology, 358–61
 - histopathology, 360–61
 - journey in mammalian host, 358–60
- protein movement across eukaryotic cell membranes, 317–22
- cytosolic chaperones, 320–21

- injection control, 321–22
 - pore formed by translocators, 319–20
 - translocation of effectors, 319
 - transported protein recognition, 321
 - Ysc secretion apparatus, 318–19
 - species of, 281–83
 - taxonomy of, 270
 - virulence factors, 346–51
 - enterotoxins, 346–47
 - fimbriae, 347–49
 - iron uptake system, 349–51
 - Yersinia aldovae*, 270, 279, 282, 406
 - Yersinia bercovieri*, 270, 279, 282–83, 406
 - Yersinia enterocolitica*, 258, 270–83, 311, 313–14, 316–19, 324–30, 332–34, 341, 345–61, 363–68, 399, 403, 406, 414–15, 418, 426, 430, 432, 569, 972
 - bacterial diagnosis of, 279–83
 - biotypes of, 282
 - clinical manifestations of, 276–79
 - gastrointestinal illness, 276
 - post-infective phenomena, 278–79
 - systemic disease, 276–78
 - epidemiology of, 271–76
 - geographical distribution, 271–72
 - large community outbreaks, 273
 - molecular, 273–75
 - reservoirs, 272
 - transmission, 272–73
 - identification of, 280
 - isolation of, 279–80
 - morphology of, 414
 - serotypes of, 335, 363–67
 - treatment for, 362
 - virulence and pathogenicity markers of, 280–82
 - Yersinia fredericksonii*, 270, 279, 282–83, 406
 - Yersinia intermedia*, 270, 282, 366, 406
 - Yersinia kristensenii*, 270, 279, 282, 406
 - Yersinia mollaretii*, 270, 279, 282–83, 406
 - Yersinia pestis*, 270–71, 279, 311, 313–14, 316–18, 325–30, 332, 345, 347–48, 358, 362, 399–433, 673
 - applications of, 433
 - biovars of, 424–25
 - characteristics of, 401–2
 - cultivation of, 408–9
 - disease of, 425–33
 - cell-mediated immunity, 428
 - humoral immunity, 428–30
 - immunity, 428
 - pathology of, 425–28
 - virulence factors for dissemination, 430–31
 - virulence factors for vegetative growth, 431–33
 - epidemiology of, 424–25
 - genetics of, 423–24
 - genome, 423
 - historical, 423
 - pgm* locus, 423–24
 - growth of, 409
 - habitats of, 406
 - identification of, 406–8
 - isolation of, 406
 - morphology of, 407, 413
 - phylogeny of, 400–405
 - physiology of, 409–23
 - chromosome-encoded functions, 416–23
 - global regulation, 411–12
 - intermediary metabolism, 409–11
 - murine toxin, 413
 - pCD-encoded functions, 414–15, 419–23, 425–26
 - pesticin, 413–14
 - pMT-encoded functions, 415–16
 - pPCP-encoded functions, 416
 - unique functions unrelated to virulence, 412–13
 - taxonomy of, 405–6
 - Yersinia pseudotuberculosis*, 270–71, 276, 278–79, 282–318, 320, 324–33, 343–53, 356, 358–61, 363–68, 399–407, 410–11, 413–15, 417–18, 422, 425–26, 430–32, 673
 - bacteriological diagnosis of, 317
 - characteristics of, 401–2
 - clinical manifestations of, 285, 316–17
 - gastrointestinal illness, 316
 - post-infective phenomena, 317
 - systemic disease, 316–17
 - epidemiology of, 283–316
 - distribution of subgroups of, 283–96
 - geographical distribution, 311–15
 - human infections, 283, 285–88, 290–91, 293, 295
 - reservoirs of, 295–305
 - seasonal distribution, 311, 313
 - transmission, 305–11
 - genetic groups of, 287–95, 304
 - plasmid of, 325–26
 - serotypes of, 283–84, 287–90, 301–4, 306–7, 313–14, 334, 363
 - superantigens of, 343–46
 - treatment for, 362
 - Yersinia rohdei*, 270, 279, 282, 406
 - Yersinia ruckeri*, 80, 270, 279, 283, 406, 412
 - Yersiniosis
 - Yersinia*, 354
 - Yersinia enterocolitica*, 272–73
 - Yersinia pseudotuberculosis*, 304
 - Yokenella*, 34, 51
 - Yokenella regensburgei*, 34
- Z**
- Zymobacter*, 813–30
 - Zymobacter palmae*, 812, 815–18
 - Zymomonas mobilis*, 181
